CHAPTER 1
Introduction 2

The Life-Span Perspective 3

The Importance of Studying Life-Span Development 3

Characteristics of the Life-Span Perspective 3

CONNECTING WITH CAREERS *Gustavo Medrano, Clinical Psychologist 7*

Some Contemporary Concerns 7

CONNECTING DEVELOPMENT TO LIFE *Improving Family Policy 11*

The Nature of Development 12

Biological, Cognitive, and Socioemotional Processes 12

Periods of Development 13

CONNECTING WITH RESEARCH *Is There a Best Time of Day to Conduct Research? 15*

The Significance of Age 17

Developmental Issues 19

Theories of Development 21

Psychoanalytic Theories 21

Cognitive Theories 23

Behavioral and Social Cognitive Theories 25

Ethological Theory 26

Ecological Theory 27

An Eclectic Theoretical Orientation 28

Research on Life-Span Development 29

Methods for Collecting Data 29

Research Designs 32

Time Span of Research 34

Conducting Ethical Research 36

Minimizing Bias 36

CONNECTING WITH CAREERS *Pam Reid, Educational and Development Psychologist 37*

Reach Your Learning Goals 39

APPENDIX
Careers in Life-Span Development 43

SECTION 2 BIOLOGICAL PROCESSES, PHYSICAL DEVELOPMENT, AND HEALTH 47

CHAPTER 2
Biological Beginnings 48

The Evolutionary Perspective 49

Natural Selection and Adaptive Behavior 49

Evolutionary Psychology 49

Genetic Foundations of Development 52

The Collaborative Gene 52

Genes and Chromosomes 54

Genetic Principles 56

Chromosomal and Gene-Linked Abnormalities 57

CONNECTING WITH CAREERS *Jennifer Leonhard, Genetic Counselor 59*

Heredity and Environment Interaction: The Nature-Nurture Debate 60

Behavior Genetics 60

CONNECTING DEVELOPMENT TO LIFE *Am I an "I" or "We"? 61*

Heredity-Environment Correlations 61

The Epigenetic View and Gene × Environment (G × E) Interaction 62

Conclusions about Heredity-Environment Interaction 63

Prenatal Development 64

The Course of Prenatal Development 64
Prenatal Diagnostic Tests 68
Hazards to Prenatal Development 69
Prenatal Care 76

Birth and the Postpartum Period 77

The Birth Process 77
The Transition from Fetus to Newborn 80

CONNECTING WITH CAREERS *Linda Pugh, Perinatal Nurse 81*

Low Birth Weight and Preterm Infants 81
Bonding 83

CONNECTING WITH RESEARCH *How Are Preterm Infants Affected by Touch? 84*

The Postpartum Period 84

Reach Your Learning Goals 87

CHAPTER 3
Physical Development and Biological Aging 90

Body Growth and Change 91

Patterns of Growth 91
Height and Weight in Infancy and Childhood 92
Puberty 93
Early Adulthood 97
Middle Adulthood 97
Late Adulthood 99

CONNECTING WITH CAREERS *Sarah Kagan, Geriatric Nurse 100*

The Brain 101

The Neuroconstructivist View 101
Brain Physiology 101
Infancy 103
Childhood 106
Adolescence 107

CONNECTING DEVELOPMENT TO LIFE *Strategies for Helping Adolescents Reduce Their Risk-Taking Behavior 109*

Adulthood and Aging 109

CONNECTING WITH RESEARCH *The Nun Study 112*

Sleep 113

Why Do We Sleep? 113
Infancy 113
Childhood 115
Adolescence and Emerging Adulthood 115
Adulthood and Aging 117

Longevity and Biological Aging 118

Life Expectancy and Life Span 118
Centenarians 120
Biological Theories of Aging 122

Reach Your Learning Goals 125

CHAPTER 4
Health 128

Health, Illness, and Disease 129

Children's Health 129
Adolescents' Health 130

CONNECTING WITH CAREERS *Bonnie Halpern-Felsher, University Professor in Pediatrics and Director of Community Efforts to Improve Adolescents' Health 131*

Emerging and Young Adults' Health 132
Health and Aging 132

CONNECTING WITH RESEARCH *How Stressful is Caring for an Alzheimer Patient at Home? 137*

Nutrition and Eating Behavior 139

Infancy 139

guide to diversity, equity, and inclusion

Special attention is given to diversity, equity, and inclusion (DEI) in this new edition, including updating preferred pronouns and terminology. Additionally, sources were cited from researchers publishing in such journals as *Current Psychology: A Journal for Diverse Perspectives on Psychological Issues,* ensuring the citations of studies and researchers represent diverse and global populations and topics. Following is a chapter-by-chapter list of the related topics along with new content and revisions involving DEI issues and research.

Chapter 1: Introduction

- Coverage of very recent projections for a decline of approximately one year in U.S. life expectancy in 2020, with a three- to four-year drop for African Americans and Latinxs because of the staggering number of deaths due to the COVID-19 pandemic (Andrasfay & Goldman, 2021)
- Updated rates of poverty that dropped considerably from 2018 to 2019 for African American, Latinx, and Asian American children and adolescents, including a much larger drop than for non-Latinx White children and adolescents (Semega & others, 2020)
- Inclusion of a recent research review of 3- to 19-year-old U.S. children and adolescents concluding that those living in low socioeconomic status (SES) settings were more likely to have higher levels of psychopathology (Peverill & others, 2021)
- Description of a recent focus of the Ascend two-generation program on the importance of parents' education, economic stability, and overall health for their children's well-being (Ascend, 2021; Aspen Institute, 2019)
- Main section, "Sociocultural Contexts and Diversity" (Kulich & others, 2021)
- Section on culture and cross-cultural studies (Bhawuk & Landis, 2021)
- Section on ethnicity (Gollnick & Chinn, 2021)
- *Connecting with Careers* profile of Gustavo Medrano, a clinical psychologist who specializes in bicultural and bilingual therapy for children, adolescents, and adults
- Content on discrimination and prejudice experienced by ethnic minority individuals (Clauss-Ehlers, Roysircar, & Hunter, 2021) including commentary about the killing of George Floyd and others by police
- Description of Adriana Umaña-Taylor and her colleagues' (Sladek, Umaña-Taylor, & others, 2020; Umaña-Taylor & Hill, 2020) research that indicates pride in one's ethnic identity group and exploration of ethnic identity development have positive outcomes
- Description of socioeconomic status and associated inequalities (Mayo & Wadsworth, 2020)
- Coverage of gender classification and transgender (Spizzirri & others, 2021)
- Discussion of social policy, including American activist Marian Wright Edelman's efforts to improve children's rights and quality of life
- Inclusion of content on the child poverty rate being higher in the United States than in other countries
- *Connecting Development to Life* interlude that includes recommendations for improving family policy in the United States (Crosby, 2021)
- Main section on reducing gender bias and cultural and ethnic bias in research on life-span development
- *Connecting with Careers* profile of Pam Reid, who has had a special interest in improving the lives of African American girls

Chapter 2: Biological Beginnings

- Inclusion of a recent study that found while XYY boys did not have more cognitive deficits than normal XY boys, they did have more externalizing and internalizing problems (Operto & others, 2019)
- New content on the number of children born worldwide with sickle-cell anemia and how stem cell transplantation is being explored in the treatment of infants with sickle-cell anemia (Cisneros & Thein, 2020)
- Coverage of a recent study in which African American and Latinx women reported almost twice as many barriers to prenatal care as non-Latinx White women (Fryer & others, 2021)
- New content on ethnic disparities in prenatal care and pregnancy with African American and Native American/Alaska Native women especially experiencing inadequate care (Petersen & others, 2019)
- Updated data on the percentage of U.S. infants who are born preterm, including ethnic variations (Martin & others, 2019)
- Updated data on the percentage of U.S. babies born with low birth weight, including ethnic variations (Martin & others, 2019)
- Cross-cultural content on the people (midwives, for example) who aid mothers in the birth of their babies

Chapter 3: Physical Development and Biological Aging

- Discussion of a recent research review of 30 studies in different countries around the world that revealed the age at which breast development began in girls (called thelarche) declined by almost 3 months per decade from 1977 to 2013 (Eckert-Lind & others, 2020)

- Coverage of a recent study that revealed menarche has been occurring at younger ages in recent years in Portugal (Queiroga & others, 2020)
- Description of a recent study of Chinese adolescents that revealed girls were more dissatisfied with their appearance than boys were, but boys were more dissatisfied with their sexual organs (Zhang & others, 2020)
- Inclusion of recent research in which higher social media use was linked to more negative body images for adolescents, more so for girls than for boys (Kelly & others, 2019)
- Updated data on gender and ethnic differences in life expectancy in the United States (Murphy & others, 2018; Xu & others, 2020)
- New discussion of the "Latinx Health Paradox," which refers to Latinxs living 3.2 years longer than non-Latinx Whites despite having lower income and less education, as well as exploration of possible reasons for this difference (Brill, 2019; Tabler & others, 2020)
- Coverage of a recent study that supported the "Latinx Health Paradox," in which older Latinx adults reported having better health than their non-Latinx White counterparts did (Olsen, Basu Roy, & Tseng, 2019)
- Description of cross-cultural variations in the experience of menopause
- Inclusion of content on poverty's role in diminishing the brain functioning of children and adolescents
- Discussion of data comparing life expectancy in the United States to life expectancy in other countries (Geoba, 2019)

Chapter 4: Health

- New content indicating that children living in poverty have higher rates of accidents, asthma, and death than children from higher-income families (Kelleher, Reece, & Sandel, 2018)
- New coverage of ethnic disparities in health coverage and chronic health conditions in U.S. children (Carratala & Maxwell, 2020)
- New *Connecting with Careers* profile of Dr. Bonnie Halpern-Felsher, University Professor of Pediatrics and Director of Community Efforts to Improve Adolescents' Health. Dr. Halpern-Felsher coordinates the STEP-UP program (Short-Term Research Experience for Underrepresented Persons), in which she has personally mentored and supervised 22 to 25 middle and high school students every year since 2007.
- New content on ethnic disparities in U.S. adults 20 years of age and older (Health United States, 2019)
- Inclusion of new data on ethnic variations in rates of Alzheimer disease (Alzheimer's Association, 2020)
- Coverage of a recent study that revealed 3- to 4-year-old African American children and children who lived at or below the poverty level were more likely than other young children to engage in more than 1 hour of screen time daily (Kracht, Webster, & Staiano, 2020)
- Discussion of recent research indicating that infants in a WIC program had higher cognitive scores on the Bayley Scales of Infant Development (Lakshmanan & others, 2020)
- New description of the special concern created by COVID-19 for young children in low-income families who attend early child-care and education programs because many states closed these programs (which provide free meals and snacks) during the pandemic (Bauer & others, 2021)
- Updated data on obesity rates for different genders and ethnicities in the United States (Hales, 2020)
- Updated data on gender and ethnic variations in exercise during adolescence (Underwood & others, 2020)
- Coverage of poverty's role in diminishing access to health care for children
- *Connecting with Careers* profile of Dr. Mustafa-Infante, who works at Mission Pediatrics in Riverside, California, and serves as a volunteer for Ayacucho Mission, a nonprofit organization that provides culturally sensitive medical care for people living in poverty in Ayacucho, Peru. In regard to her cultural background, Dr. Mustafa-Infante describes herself as a Latina doctor who has a Middle-Eastern name, reflecting her strong family commitments to both heritages.
- Discussion of cross-cultural comparisons of adolescents' consumption of fast food
- Description of ethnic variations in overweight and obesity in the United States as well as cross-cultural comparisons

Chapter 5: Motor, Sensory, and Perceptual Development

- Recent research involving urban, predominately Latinx 6- to 11-year-olds that found low sports participation was linked to higher withdrawn and depressive symptoms (Matta & others, 2021)

Chapter 7: Information Processing

- Description of recent research with 8- to 18-month-old infants that revealed those from higher-SES families responded to more sophisticated cues for joint attention than infants from lower-SES families (Reilly & others, 2021)
- Inclusion of a recent study that revealed Latinx older adults who were more acculturated in the United States had better working memory than their less acculturated counterparts (Mendoza & others, 2021)
- Discussion of a recent study of older Mexican adults that revealed in addition to one's own education, a spouse's education also was associated with better cognitive ability (Saenz & others, 2020)
- Inclusion of a recent study of Puerto Rican older adults that found a higher level of cognitive complexity in work was associated with a lower risk of cognitive impairment (Andel & others, 2019)
- Description of a recent study of older Latinxs in which cardiovascular risk factors were linked to lower cognitive functioning (Tarraf & others, 2020)

Chapter 8: Intelligence

- Discussion of a recent study of 22 countries (including Argentina, China, France, India, Peru, Turkey, and the United States) that found variations in intelligence across countries

were linked to income, educational attainment, health, and socioeconomic status (Lynn, Fuerst, & Kirkegaard, 2018)
- Coverage of cross-cultural variations in the Flynn Effect
- Content describing the increasing research interest in programs that seek to improve the experiences of children with low IQs, especially those in low-income circumstances (Schianti, Simeonsson, & Hall, 2021)
- *Connecting with Research* interlude exploring whether early intervention with children who are growing up in impoverished circumstances might improve their intelligence.
- Section on cross-cultural comparisons in intelligence
- Content on cultural bias in intelligence testing
- Discussion of research on stereotype threat, including recent content on studies that support the concept of stereotype threat (Crosby, 2021)
- Inclusion of content on culture-fair tests
- Description of ethnic variations in intelligence
- Coverage of Donna Ford's (2015a, b) view that African American, Latinx, and Native American children are underrepresented in gifted programs. Much of the underrepresentation involves the lower test scores for these children compared with non-Latinx White and Asian American children, which may be due to factors such as test bias and fewer opportunities to develop language skills such as vocabulary and comprehension.

Chapter 9: Language Development

- New discussion of English-speaking preschool children that revealed those from lower-income families had less advanced language-processing skills, as well as a smaller vocabulary and syntax deficiencies (Levine & others, 2020)
- Inclusion of recent research with low-income families in which 15-month-old infants whose mothers had a college education had much better language skills than their low-income counterparts whose mothers did not have a college education, and these differences were still present at 3 years of age (Justice & others, 2020)
- Coverage of a recent meta-analysis in which sensitive responsiveness by parents in low-SES families was more strongly linked to improvement in young children's language development than was the case in middle- and high-SES families (Madigan & others, 2019)
- Description of a recent study that found children living in extreme poverty had much lower vocabulary and reading comprehension (Lervag & others, 2019)
- New *Connecting with Research* interlude on the effects of communication difficulties between hearing parents and deaf children
- Cross-cultural research indicating that English is a noun-friendly language, while Korean and other Asian languages are verb-friendly languages
- *Connecting with Careers* profile of Sharla Peltier, a speech therapist in Manitoulin, Ontario, Canada, who works with Native American children in First Nations schools
- Discussion of research indicating that the extent to which phonological awareness is linked to reading skills varies across different languages
- Inclusion of recent research that found stronger Spanish language skills at 2 years of age were linked to better English language skills as well as maintenance of good language skills at 4.5 years of age (Marchman & others, 2020). These findings indicate that families who primarily speak Spanish should engage in activities that develop children's competence in Spanish while also encouraging opportunities to learn English.
- Coverage of the best way to teach English language learners (ELLs), many of whom in the United States are from immigrant families living in poverty
- *Connecting with Careers* profile of Salvador Tamayo, an ELL fifth-grade teacher at Turner Elementary School in West Chicago. He received a National Educator Award from the Milken Family Foundation for his work in educating ELLs, and he and his students have created several award-winning websites about the West Chicago City Museum, the local Latinx community, and the history of West Chicago.

Chapter 10: Emotional Development and Attachment

- Discussion of a recent study of low-income families in which having a difficult temperament at 0 to 12 months of age predicted behavior problems at 36 months (Maltby & others, 2019)
- Coverage of a recent study in which Latinx infants were at increased risk for obesity if their mothers had an anxious or avoidant insecure attachment style rather than a secure attachment style (Hepworth & others, 2021)
- Description of a recent cross-cultural study of more than 7,000 individuals in 25 countries that found support for the universality of Sternberg's triarchic theory of love (Sorokowski & others, 2021)
- Inclusion of cultural variations in emotional development (Suarez-Alvarez & others, 2020)
- Section on gender, culture, and temperament
- Discussion of Chinese children being more inhibited than U.S. and Canadian children
- Content on cross-cultural studies of attachment
- Description of the Aka pygmy culture in which fathers spend as much time as mothers in caring for infants
- Inclusion of content on cross-cultural comparisons of child care in which many European countries, especially those in Scandinavia, have led the way in providing government-funded child care
- *Connecting with Careers* profile of Wanda Mitchell, Center Director of the Hattie Daniels Day Care Center in Wilson, North Carolina
- Coverage of cross-cultural variations in dating, such as greater parental restrictions on dating for African American and Latinx adolescents than for non-Latinx White adolescents
- Discussion of cross-cultural variations in adult romantic relationships

Chapter 11: The Self, Identity, and Personality

- Description of a recent study in three countries—Brazil, Portugal, and Spain—that found parental warmth was a key factor in adolescent self-esteem in all three countries (Isabel Martinez & others, 2020)
- Inclusion of a longitudinal study with Mexican-origin adolescents that found a reciprocal relation between self-esteem and academic achievement (Zheng & others, 2020)
- Section on cross-cultural variations in identity development including the greater collectivist emphasis in Asian countries on fitting in with the group and connecting with others (Schwartz & others, 2020)
- Greatly expanded and updated content on ethnic and racial identity based on feedback from leading expert Kevin Cokley
- Content on bicultural identity, especially in different generations of U.S. immigrants
- New coverage of racial identity
- Inclusion of recent research on 13- to 17-year-old African American girls' racial socialization in which pride was linked to positive feelings about being Black, while oppressive messages about Black women were associated with depressive feelings (Stokes & others, 2020)
- Description of a recent study of 11- to 12-year-olds that found more frequent discrimination from peers was linked to lower ethnic-racial commitment (Del Toro, Hughes, & Way, 2021)
- Coverage of a recent study of adolescents that revealed on days when adolescents reported more negative peer ethnic/racial interaction, they had lower school engagement (Wang, 2021). Also in this study, on days when they reported more positive peer ethnic/racial interaction, they engaged in more prosocial behavior.
- Inclusion of a recent research review of Latinxs that concluded perceived discrimination was linked to poorer mental health but having a greater sense of ethnic pride attenuated this link (Andrade, Ford, & Alvarez, 2021)
- New discussion of the singular concept of ethnic-racial identity (ERI) (Atkin & others, 2021)
- Description of a recent study of Cherokee young adolescents' ERI that revealed both girls and boys reported strong positive attitudes about being a Cherokee (Hoffman, Kurtz-Coates, & Shaheed, 2021). However, youths' perceptions that others hold Cherokees in high regard decreased across the years.
- Coverage of a recent study that found Latinx youth had greater resilience in response to discrimination when they had more experiences with ethnic family socialization and had engaged in ethnic identity exploration and resolution (Martinez-Fuentes, Jager, & Umaña-Taylor, 2021)
- Discussion of a recent study of Latinx young adolescents that found higher resilience and school attachment predicted higher optimism (Taylor & others, 2020)
- Description of a recent study that revealed regardless of growing up in disadvantaged circumstances as a child, being optimistic as an adult was linked to being a non-smoker, having a healthy diet, and having a healthy body mass index (Non & others, 2020)
- New *Connecting with Research* interlude exploring whether an individual's personality profile is linked to their diversity orientation and attitudes about diversity

Chapter 12: Gender and Sexuality

- Extensive editing, revision, and updating based on leading expert Sabra Katz-Wise's feedback and comments, with special attention to contemporary use of various gender-related terms
- New *Connecting with Research* interlude focusing on what preschool children think about gender and careers
- Coverage of a recent study of 3- to 7-year-olds that found boys were more likely to engage in gender stereotyping than girls, especially with masculine stimuli such as toys, and to be sanctioned for not conforming to gender stereotypes (Skocajic & others, 2020)
- New commentary pointing out that categories such as gender and ethnicity intersect and create systems of power and privilege as well as oppression and discrimination
- Extensively edited, expanded, and updated coverage of transgender individuals
- New discussion of the term *two-spirit* that is used by some indigenous North Americans to refer to individuals who are perceived as having both male and female spirits within them
- New content indicating that 40 percent or more of transgender individuals have attempted suicide at least once in their lifetime (Dickey & Budge, 2020)
- Coverage of a recent study of transgender individuals in which gender affirmation was associated with a lower rate of suicidal ideation and psychological distress, while gender discrimination was linked to a higher rate of suicidal ideation and psychological distress (Lelutiu-Weinberger, English, & Sandanpitchai, 2020)
- Description of recent research that confirmed victimization and discrimination predicated increased suicidal ideation in transgender individuals, while community connectedness reduced suicidal ideation (Rabasco & Andover, 2021)
- Inclusion of a recent study that found a majority of transgender persons had experienced discrimination in the previous year and that those who encountered greater discrimination were more likely to develop depression and anxiety symptoms (Puckett & others, 2020)
- New commentary noting that because trans individuals experience considerable discrimination, it is important that society provide a more welcoming and accepting attitude toward them (Vargas, Huey, & Miranda, 2020)
- Coverage of a recent study that found psychotherapy targeting internalized stigma and non-affirmation experiences can be effective in reducing gender-related stress and increasing resilience (Budge, Sinnard, & Hoyt, 2020)
- New *Connecting with Careers* feature on Dr. Stephanie Budge, psychotherapist and researcher focusing on transgender issues
- Updated data on the number of people in the U.S. living with an HIV infection (1.2 million), with 1 in 7 of these individuals unaware that they have the infection (HIV.gov, 2020)
- Updated statistics indicating that in 2018, approximately 36,400 new HIV infections were diagnosed, with 69 percent

of those diagnoses occurring in men who were having sex with other men (HIV.gov)

- New content on the increasing interest in PrEP (pre-exposure prophylaxis) awareness, which involves taking a daily pill that can reduce the probability of getting HIV by as much as 90 percent (Restar & others, 2020)
- Coverage of a recent study that indicated women who had experienced sexual assault were more likely to subsequently have more academic problems and engage in fewer serious romantic relationships while in college and nine years later had more symptoms of depression, anxiety, and post-traumatic stress disorder (Rothman & others, 2020)
- Inclusion of recent research on acquaintance rape of college women that revealed 84 percent of the women knew their perpetrator and 65.5 percent encountered the perpetrator after the attack (Bell, Wolff, & Skolnick, 2021). Women who encountered their perpetrator after the attack reported more lifestyle changes and more severe symptoms of post-traumatic stress disorder.
- New content on the recent movement on many college campuses toward obtaining *affirmative consent* before engaging in sexual activity (Goodcase, Spencer, & Toews, 2020)
- Discussion of a recent study of young adults in which women (37.4 percent) were more likely to report having experienced sexual assault than men (22.4 percent) (Mumford & others, 2020)
- Updated national data (2019) from the Youth Risk Behavior Surveillance study on the timing of sexual intercourse in U.S. adolescents, including ethnic variations and the percentage of adolescents who have had sexual intercourse prior to 13 years of age (Underwood & others, 2020)
- Updated data on ethnic variations in the incidence of adolescent pregnancy, with significant declines among Latinx, African American, non-Latinx White, and Asian American adolescents (National Center for Health Statistics, 2019)
- Coverage of recent research on the percentage of adolescents who use condoms when they have sex, including ethnic variations (Szucs & others, 2020)
- Description of a study conducted from 2010 to 2017 that found increased use of long-acting reversible contraception (LARC), particularly by urban, educated, and higher-income women (Beshar & others, 2021)
- Update on AIDS incidence worldwide, with 88 percent of all children and adolescents with AIDS living in sub-Saharan Africa (UNAIDS, 2020)
- Updated data on ethnic variations in adolescent pregnancy, including declining rates of pregnancy in ethnic minority adolescents (Martin & others, 2021)

Chapter 13: Moral Development, Values, and Religion

- Inclusion of recommendations by leading expert Gustavo Carlo, whose many research studies focus on international groups and U.S. ethnic/racial groups, especially Latinx youth and families
- New *Connecting with Research* interlude on how parent and peer relationships influence Latinx adolescents' prosocial behavior
- New main section, "Culture"
- Description of differences in behavior between WEIRD (Western, Educated, Industrialized, Rich, and Democratic) cultures that emphasize individual rights and independent behavior and non-WEIRD cultures that are characterized by duty-based communal obligations and collective, interdependent behavior
- New coverage of the importance of familism in the moral development of children in Mexican and Latinx families (Carlo & Pierotti, 2020)
- Discussion of differences in morality within a culture, such as differences between people living in lower- and higher-SES contexts
- Inclusion of a recent study in 12 countries that found sharing increased from 4 to 12 years of age in each of the countries (Samek & others, 2020)
- Description of a recent study of lesbian and gay older adults that revealed those who engaged in volunteer work had better physical health, more positive mental health, and less psychological distress (Lyons & others, 2021)
- New content on a recent study that found neighborhood poverty was linked to delinquency in adolescence, especially through maternal stress and adverse childhood experiences (Wang, Choi, & Shin, 2020)

Chapter 14: Families, Relationships, and Parenting

- Main section, "Sociocultural and Historic Influences"
- New data indicating that African American adults (47 percent) are much more likely to be single than non-Latinx White adults (28 percent) and Latinx adults (27 percent) (Brown, 2020)
- New content indicating that at lower SES levels, couples are more likely to cohabit and give birth prior to marriage and less likely to marry at all (Karney, 2021)
- New content noting that cohabitation is increasing in China and Taiwan but still rare in Japan and South Korea
- Coverage of a recent study that found men had a higher level of marital satisfaction than women across a number of countries (Sorokowski, Kowal, & Sorokowska, 2019). In this study, marital satisfaction was similar among Muslims, Christians, and atheists.
- New comparison of age at first marriage in a number of developed countries, with individuals in Sweden getting married latest and those in Israel and Turkey earliest
- New content and data on the percentage of individuals from different ethnic groups who are married (U.S. Census Bureau, 2019)
- New content and data on the percentages of newlyweds and all married people who are married to someone from a different ethnic group, percentages that have dramatically increased in recent years (Livingston & Brown, 2017)
- Coverage of recent research on Mexican married older adults in which spousal support was associated with less loneliness while spousal strain was linked to more loneliness three years later (Saenz, 2021)

- New content on ethnic variations in divorce rates, including the fact that among Latinxs, 30 percent of women and 27 percent of men become divorced in their lifetime
- Section on contextual aspects of parenting styles, including an explanation of Ruth Chao's term "training parents" in reference to the parenting style found in many Asian American families
- Discussion of cross-cultural variations in the use of corporal punishment
- New data on the increasing number of countries that are banning the use of corporal punishment (Global Initiative to End All Corporal Punishment of Children, 2020)
- Description of gender and ethnic variations in parental granting of autonomy to adolescents (Tran & Rafaelli, 2020)
- Discussion of the influence of socioeconomic status in the lives of children in divorced families
- Inclusion of recent research indicating that lesbian mothers, heterosexual mothers, and gay fathers reported higher parenting competence than heterosexual fathers (Farr & Vazquez, 2020a)
- Coverage of a U.K. longitudinal study of gay father, lesbian mother, and heterosexual parent families when their children reached early adolescence that found few differences among the three family styles and concluded that better parenting quality and parental mental health were linked to fewer adolescent problems (McConnachie & others, 2021)
- Section on the changing landscape of adoptive parents and adopted children in terms of diversity in a number of areas
- New *Connecting with Research* interlude on potential roles of school counselors in working with transracially adopted children and adolescents

Chapter 15: Peers and the Sociocultural World

- Coverage of a recent study in the United States and China that found parents' increased restriction of peer interaction predicted a decrease in children's adjustment over time (Xiong & others, 2020)
- Description of a recent study of more than 15,000 U.S. high school students that found African American and Latinx adolescents were less likely to have experienced school bullying and cyberbullying than non-Latinx White adolescents (Webb & others, 2021)
- Main section on the relevance of culture for the study of life-span development
- Section on individualist and collectivist cultures, including a number of relevant research studies
- Expanded coverage of what the term *culture* means, including content on how everyone has a culture (with multiple examples provided)
- Description of the World Health Organization's (WHO) recommendation that 3- to 4-year-old children should engage in no more than 1 hour of screen time daily (Willumsen & Bull, 2020)
- Inclusion of recent research on 13- to 18-year-olds in the United States and the United Kingdom that revealed significant gender differences in the types of digital media they used (Twenge & Martin, 2020)
- Discussion of a recent large-scale study of more than 32,000 15-year-olds in 37 countries that found problematic social media use and low social support were the best predictors of low levels of satisfaction with life (Walsh & others, 2020)
- Section on aging and culture that includes comparisons of different cultures' views of aging
- Main section on socioeconomic variations in families and neighborhoods
- Main section on consequences of socioeconomic status for children and adolescents
- Coverage of a recent study in which lower SES was linked to less cortical surface area in the brains of adolescents as well as less effective working memory (Judd & others, 2020). The SES factor most responsible for the lower level of brain functioning was less parental education.
- Inclusion of a recent Chinese study that found low family SES was linked to children's low academic achievement, with a key factor being low parental involvement in children's schooling (Zhang & others, 2020)
- Main section on poverty
- Updated data on the percentage of U.S. adults below the poverty line with varying degrees of education (Duffin, 2019)
- Updated data on the percentage of single-mother families living in poverty (34 percent), which was nearly 5 times that of their married counterparts (6 percent) (U.S. Census Bureau, 2019)
- Coverage of intervention studies that seek to improve the lives of children and adolescents living in poverty conditions
- Section on SES, poverty, and aging
- Inclusion of a recent study of older adults in which poverty was a risk factor for earlier death (Guimaraes & Andrade, 2020)
- Main section on ethnicity
- New opening commentary in the section on ethnicity focusing on the importance of not using a deficit model in studying ethnic minority adolescents and of recognizing not just stressors but also the positive aspects of their lives (Weissmark & others, 2020)
- Updated data on the percentage of children and adolescents (18 and younger) from different ethnic groups in the United States (U.S. Census Bureau, 2018)
- New discussion of Yoonsun Choi and her colleagues' (Choi & Hahn, 2017; Choi & others, 2020a, b, c) research on generational differences in Filipino Americans and Korean Americans, as well as younger Asians' belief that older Asians place too much emphasis on education
- Coverage of a recent study in which immigrant children who were separated from their parents had lower literacy skills and more psychological problems than those who had migrated with their parents (Lu, He, & Brooks-Gunn, 2020). Also in this study, a protracted period of separation and prior undocumented status of parents further increased the children's disadvantages.
- New content on multi-ethnic/racial individuals and the discrimination they often encounter (Tan & others, 2019; Woo & others, 2020)

- New description of the positive outcomes when adolescents have a positive ethnic identity (Umaña-Taylor & others, 2020)
- Inclusion of content on how Latinx families are embracing the importance of education in their children's and adolescents' development
- New discussion of a recent study in which Latinx adolescents showed enhanced resilience against discrimination encounters when they had more family ethnic socialization experiences and engaged in greater identity exploration and resolution (Martinez-Fuentes, Jager, & Umaña-Taylor, 2021)
- Coverage of how poverty affects the development of ethnic minority children and adolescents
- New main section, "Racism and Discrimination"
- New coverage of Black Lives Matter and the killing of George Floyd in Minneapolis as well as discussion of past and current examples of racism and discrimination in the United States
- New discussion of how to talk with children about racism based on the Intentional Parenting for Equity and Justice program proposed by Diane Hughes and her colleagues (Hughes, Fisher, and Cabrera, 2020)
- Inclusion of new content based on BIPOC (Black, Indigenous, and other People of Color) parents' emphasis on how their children and youth can stay safe during interactions with the police
- Recommendation of a recent book that helps BIPOC parents talk with their children and youth about race: *The ABCs of Survival* (National Black Child Family Institute, 2021)
- New quotation from Mahatma Gandhi: "Our ability to reach unity in diversity will be the beauty and the test of our civilization"
- New content on the dramatic increase in ethnic diversity that is predicted to occur among older adults (U.S. Census Bureau, 2019)
- Section on ethnicity and aging
- *Connecting with Careers* feature on Norma Thomas, social work administrator and educator
- New data indicating that poverty rates for African American older adults have declined since 1975 but are still far too high (Congressional Research Service, 2019)

Chapter 16: Schools, Achievement, and Work

- New coverage of an experimental study with young children in a high-poverty area that found those who attended Montessori programs over a three-year period fared better in academic achievement, social understanding, and mastery orientation than those who attended other early childhood programs (Lillard & others, 2017)
- Description of a recent study in which a social-emotional learning program and a coordinated interactive reading program were used to enrich Head Start curricula, an intervention that resulted in the children having significantly fewer conduct problems and negative emotional symptoms, as well as better peer relations in adolescence (Bierman & others, 2021)
- Coverage of a recent study of 3- to 4-, 5- to 6-, and 8- to 9-year-olds that found children in foster care who participated in Head Start programs had better cognitive, socioemotional, and health outcomes than their foster care counterparts who did not attend Head Start programs (Lee, 2020)
- Updated data on school dropout rates, which continue to drop considerably (National Center for Education Statistics, 2020)
- Description of recent research that found African American children and adolescents are being classified with ADHD more than non-Latinx Whites and Latinxs (Zablotski & Alford, 2020)
- Inclusion of recent research indicating that African American children and adolescents with ADHD are often underdiagnosed while those engaging in disruptive behavior are often over-diagnosed (Fadus & others, 2020)
- Coverage of recent research indicating that low socioeconomic status is linked to ADHD and inferior brain functioning (Machlin, McLaughlin, & Sheridan, 2020)
- New content on the dramatic increase in the percentage of children who are autistic (Centers for Disease Control and Prevention, 2020) and the percentage of autistic children who are receiving special education services (National Center for Education Statistics, 2020)
- Inclusion of the 2019 Trends in International Mathematics and Science Study (TIMSS) of math and science achievement in a number of countries, with East Asian countries taking 19 of the top five spots in fourth- and eighth-grade science and fourth- and eighth-grade math. Singapore was number one in three of the four comparisons.
- Update on the percentage of full-time and part-time students who are working while going to college (National Center for Education Statistics, 2018)
- Discussion of a recent analysis indicating that healthy, well-educated, high-income older adults can continue working longer than lower-income older adults who work in physically demanding jobs (United Income, 2019)
- New *Connecting with Research* interlude on the relationship between parental expectations and Black boys' math scores

Chapter 17: Death, Dying, and Grieving

- Cross-cultural comparisons of death in multiple places in the chapter
- Description of the countries in the world where assisted suicide is legal
- Updated data on the percentage of U.S. adolescents who seriously consider suicide each year and attempt suicide each year, including gender and ethnicity figures (Underwood & others, 2020)
- Cross-cultural comparisons of adolescent suicide
- Updated data on gender and ethnic differences in adult suicides, with males and Native Americans/Alaska Natives having the highest suicide rates (National Center for Health Statistics, 2020)
- Ethnic comparisons of suicide in adulthood
- Discussion of a recent study of 38 countries in which early sexual intercourse (at 12 to 15 years of age) in 32 of the countries was linked to increased suicide attempts, and having sexual intercourse with multiple partners increased the risk further (Smith & others, 2020)
- Inclusion of a recent research review of widowed Latinxs that found risk factors for diminished well-being were being a man, undergoing financial strain, experiencing cultural stressors, having an undocumented legal status, losing one's partner at a younger age, and having poor physical health (Garcini & others, 2021)

about the author

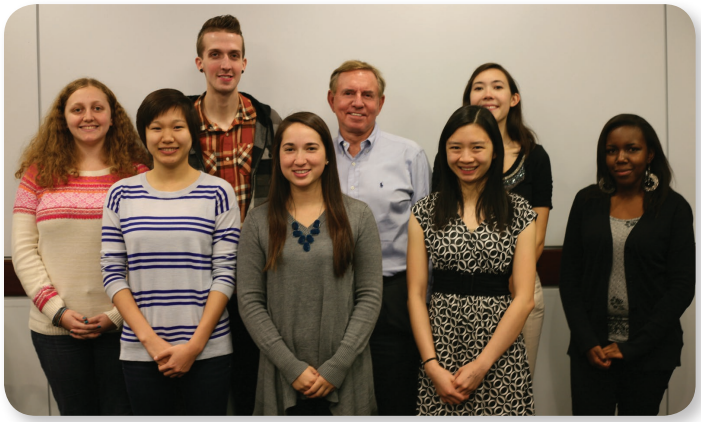
John W. Santrock

John Santrock received his Ph.D. from the University of Minnesota in 1973. He taught at the University of Charleston and the University of Georgia before joining the program in Psychology in the School of Behavioral and Brain Sciences at the University of Texas at Dallas, where he currently teaches a number of undergraduate courses and has received the University's Effective Teaching Award.

In 2010, he created the UT-Dallas Santrock undergraduate travel scholarship, an annual award that is given to outstanding undergraduate students majoring in developmental psychology to enable them to attend research conventions. In 2019, he created an endowment that will provide the travel awards for students at UT-Dallas for decades to come. Additionally, Dr. Santrock and his wife, Mary Jo, created a permanent endowment that will provide academic scholarships for six to ten undergraduate psychology students per year, with preference given to those majoring in developmental psychology.

John has been a member of the editorial boards of *Child Development* and *Developmental Psychology.* His research on father custody is widely cited and used in expert witness testimony to promote flexibility and alternative considerations in custody disputes. He also has conducted research on children's self-control. John has authored these exceptional McGraw Hill texts: *Psychology* (7th edition), *Children* (15th edition), *Child Development* (15th edition), *Adolescence* (18th edition), *Life-Span Development* (18th edition), and *Educational Psychology* (7th edition).

For many years, John was involved in tennis as a player, teaching professional, and a coach of professional tennis players. As an undergraduate, he was a member of the University of Miami (FL) tennis team that still holds the record for most consecutive wins (137) in any NCAA Division I sport. John has been married for four decades to his wife, Mary Jo, who created and directed the first middle school program for children with learning disabilities and behavioral disorders in the Clarke County Schools in Athens, Georgia, when John was a professor at the University of Georgia. More recently, Mary Jo has worked as a Realtor. John and Mary Jo have two daughters—Tracy and Jennifer—both of whom are Realtors after long careers in technology marketing and medical sales, respectively. In 2016, Jennifer became only the fifth female to have been inducted into the SMU Sports Hall of Fame. John and Mary Jo have one granddaughter, Jordan, age 28, who completed her master's degree from the Cox School of Business at SMU and currently works for Ernst & Young, and two grandsons—the Belluci brothers: Alex, age 16, and Luke, age 15. In the last decade, John also has spent time painting expressionist art.



John Santrock (back row middle) with recipients of the Santrock Travel Scholarship Award in developmental psychology. Created by Dr. Santrock, this annual award provides undergraduate students with the opportunity to attend a professional meeting. A number of the students shown here attended the meeting of the Society for Research in Child Development.

With special appreciation to my mother, Ruth Santrock, and my father, John Santrock.

expert consultants

Life-span development has become an enormous, complex field, and no single author, or even several authors, can possibly keep up with all of the rapidly changing content in the many periods and different areas in this field. To solve this problem, author John Santrock has sought the input of leading experts about content in a number of areas of life-span development. These experts have provided detailed evaluations and recommendations in their area(s) of expertise.

The following individuals were among those who served as expert consultants for one or more of the previous editions of this text:

Karen Adolph
David Almeida
Karlene Ball
John Bates
Martha Ann Bell
Jay Belsky
James Birren
Dante Cicchetti
Pamela Cole
Kirby Deater-Deckard
Susanne Denham
James Garbarino
Linda George
Gilbert Gottlieb
Elena Grigorenko
Scott Hofer
William Hoyer
Janet Shibley Hyde
Rachel Keen
Jennifer Lansford
James Marcia
Linda Mayes
Patricia Miller
David Moore
Daniel Mroczek
Darcia Narváez
Charles Nelson
Crystal Park
Denise Park
Ross Parke
Glenn Roisman
Carolyn Saarni
K. Warner Schaie
Robert J. Sternberg
Elizabeth Stine-Morrow
Ross Thompson
Doug Wahlsten
Allan Wigfield
Philip David Zelazo

Following are the expert consultants for the eleventh edition, who (like those of previous editions) literally represent a *Who's Who* in the field of life-span development.

James Graham Dr. James Graham is a leading expert on the community aspects of ethnicity, culture, and development. He obtained his undergraduate degree from Miami University and received master's and doctoral degrees in developmental psychology from the University of Memphis. Dr. Graham's current position is Professor of Psychology, The College of New Jersey (TCNJ). His research addresses the social-cognitive aspects of relationships between group and dyadic levels across developmental periods in community-based settings. Three interdependent dimensions of his research program examine (1) populations that are typically understudied, conceptually limited, and methodologically constrained; (2) development of empathy and prosocial behavior with peer groups and friends; and (3) developmental science in the context of community-engaged research partnerships. Currently, he is Coordinator of the Developmental Specialization in Psychology at TCNJ. For a decade, Dr. Graham taught graduate courses in psychology and education in Johannesburg, South Africa, through TCNJ's Graduate Summer Global Program. He is the co-author of *The African American Child: Development and Challenges* (2nd ed.) and *Children of Incarcerated Parents: Theoretical, Developmental, and Clinical Issues*. Dr. Graham has presented his work at a variety of international and national conferences and has published articles in a wide range of journals, including *Social Development*, *Child Study Journal*, *Behavior Modification*, *Journal of Multicultural Counseling and Development*, and *American Journal of Evaluation*.

"John Santrock seamlessly integrates the latest research on children's, adolescents', and adults' physical, cognitive, and social processes in an ever-evolving multicultural society. In the newest edition of the book, Santrock systematically connects with students across multiple learning modalities to the latest research, developmental processes, and real-world phenomena personally and professionally. This book is an excellent resource for students in psychology and other social science fields. Once again, I am impressed with Santrock's sensitivity to the impact of culture, ethnicity, and socioeconomic status on child and adolescent development. Today, this is particularly important as we navigate the effects of events such as the coronavirus pandemic and movements for diversity, equity, and inclusion across various contexts. This text will be a great start to becoming a bit more knowledgeable and aware of the challenges and opportunities people will encounter in this increasingly multicultural society. This text will help students learn to analyze, compare, and contrast alternative perspectives of individuals domestically and globally with the major principles and theories of life-span development in cognitive, socio-emotional, and social/contextual domains. This text will also help students understand the latest research regarding societal values about ethnicity, socioeconomic, and gender issues in development and how they influence individual development and shape social policy in our increasingly diverse culture."
–James Graham, The College of New Jersey

Amanda Rose Dr. Amanda Rose is a leading expert on children's socioemotional development. She currently is a Professor in the Department of Psychological Sciences at the University of Missouri–Columbia. Dr. Rose obtained her doctorate in developmental psychology from the University of Illinois. Her research focuses on friendships in childhood and adolescence, with particular attention to differences between girls and boys and to implications for emotional adjustment. She has published in a wide range of journals, including *Developmental Psychology*, *Child Development*, and *Psychological Bulletin*, and has held grants from the National Institute of Mental Health. Dr. Rose was awarded the Early Scientific Achievement Award from the Society for Research in Child Development and recently was awarded the University of Missouri's Chancellor's Award for Outstanding Research and Creative Activity. She also recently became a fellow in the American Psychological Association.

"The chapters 'Gender and Sexuality' and 'Peers and the Sociocultural World' have a strong framework and are clear and well-written at the stage appropriate for students at this level. I was pleased with the extent to which the chapters addressed diversity, in terms of race/ethnicity, SES, and culture. I thought the chapters did a great job at covering contemporary work. If I were teaching life-span development, I would definitely consider using John Santrock's 11th edition of A Topical Approach to Life-Span Development.*"*

–Amanda Rose, University of Missouri–Columbia

(photo): University of Missouri, College of Arts & Science

Koraly Pérez-Edgar

Dr. Koraly Pérez-Edgar is a leading expert on children's and adolescent's socioemotional development. She is currently the McCourtney Professor of Child Studies and a Professor of Psychology at Penn State University. Dr. Pérez-Edgar obtained her master's degree and Ph.D. from Harvard University. Her research examines trajectories of early socioemotional development from infancy through adolescence, focusing on early-appearing temperament traits and their impact on the ways children respond to and engage with their environment. Dr. Pérez-Edgar has taken a multi-method approach to her research that involves direct observation of behavior, cognitive measures, stationary and mobile eye-tracking, psychophysiology, and neuroimaging. She is a Fellow of the Association for Psychological Science (APS) and the recipient of numerous awards, including a Cattell Sabbatical Award. Dr. Pérez-Edgar also is an associate editor of the leading journals *Child Development* and *Emotion*. In addition, she is the co-editor with Nathan Fox of *Behavioral Inhibition: Integrating Theory, Research, and Clinical Perspectives* and co-editor with Vanessa LoBue and Kristin Buss of *The Handbook of Emotional Development*.

"John Santrock's A Topical Approach to Life-Span Development *encompasses the core constructs of life-span development in a way that is both engaging and rigorous. The discussions are concrete so that new students can understand and internalize the complex constructs. However, the text then places these constructs in a more conceptual context, which should help students draw a more nuanced view of how aspects of development are multidimensional and interconnected within individuals, across contexts, and across time."*

–Koraly Pérez-Edgar, Penn State University

(photo): Courtesy Koraly Pérez-Edgar

Susan Courtney

Dr. Susan Courtney is a leading expert in cognitive neuroscience. She obtained her Ph.D. in Bioengineering from the University of Pennsylvania and then did postdoctoral training in cognitive neuroscience and neuroimaging at the National Institute of Mental Health in Bethesda, Maryland. Dr. Courtney is currently Professor of Psychological and Brain Sciences at Johns Hopkins University. Her research focuses on the neural systems underlying attention, working memory, and cognitive control in young healthy adults, older adults, and individuals with multiple sclerosis. Dr. Courtney's research involves a combination of methodologies, including cognitive behavioral analysis, functional magnetic resonance imaging, diffusion imaging, and electroencephalography. Her current research projects seek to understand individual differences in cognitive performance, specifically addressing why cognitive abilities are preserved in some older individuals and substantially decline in others. The research focuses on the role of rapid, task-related changes in synchronized oscillatory activity that enables communication of currently relevant information among distant brain areas. The goal of this research is to understand and potentially prevent or ameliorate aging-related cognitive decline. Dr. Courtney is a member of the Society for Neuroscience and the Organization for Human Brain Mapping and serves as a reviewer of manuscripts for multiple journals, as well as of grants for the NIH, NSF, and other organizations. Her research has been published in leading research journals, such as *Science*, *Nature*, *Neuron*, and *Neurobiology of Aging*.

"Overall, the strength of the text reflected in the two chapters I read ('Physical Development and Biological Aging' and 'Information Processing') includes the very broad perspective covering a wide range of topics related to development and aging. The inclusion of many specific research results also is a strength. . . . There has clearly been an effort by John Santrock to include many recent examples of important research findings."

–Susan Courtney, Johns Hopkins University

Gustavo Carlo

Dr. Gustavo Carlo is leading developmental scholar who studies children' and adolescents' prosocial and moral development. He obtained his Ph.D. from the Department of Psychology at Arizona State University and currently is Professor at the School of Education at the University of California–Irvine. He was previously the Millsap Endowed Professor of Diversity and Multicultural Studies at the University of Missouri–Columbia and Distinguished Professor at the University of Nebraska–Lincoln. His research on prosocial and moral development focuses on parenting, sociocognitive, socioemotive, and culture-related (discrimination, values, and ethnic identity, for example) influences. Many of his projects focus on international groups and U.S. ethnic/racial groups, including Latinx youth and families. Dr. Carlo has published more than 200 books, chapters, and research papers; received research grants from several agencies, including the NSF, NIH, and Templeton Foundation; and serves on multiple journal editorial boards. He is a Fellow of the American Psychological Association and the American Psychological Society. In 2018, he received the Outstanding Mentor Award from the Society for Research on Adolescence. Dr. Carlo currently serves as a member of Governing Council of the Society for Research in Child Development, as Associate Editor of the *International Journal of Behavioral Development*, and as co-editor of the forthcoming *APA Handbook of Adolescent Development*.

"The chapter 'Moral Development, Values, and Religion' has good breadth and depth. It's great to see the integrative approach, which covers prosocial, moral, and religious development in one chapter. The chapter 'Peers and the Sociocultural World' has excellent coverage of peer influence. . . . the chapters provide a great overview of major theories and research."

–Gustavo Carlo, University of California–Irvine

(photo): Courtesy of Gustavo Carlo

Virginia Marchman

Dr. Virginia Marchman is a leading expert on children's language development. She currently is a Research Associate at the Stanford University Language Learning Laboratory and obtained her Ph.D. at the University of California–Berkeley. Her main research areas are language development, language disorders, and early childhood development. Dr. Marchman's specific interests focus on individual differences in typically-developing and late-talking children, as well as lexical and grammatical development in monolingual and bilingual learners. Her studies have incorporated a variety of experimental methods as well as computational approaches and naturalistic observation. Dr. Marchman has worked extensively with the MacArthur-Bates Communicative Development Inventories (CDI), developing the CDI Scoring program and serving

on the MacArthur-Bates CDI Advisory Board. She has been a consulting editor for the *Journal of Speech, Language & Hearing Research* and *Child Development*. Her most recent work involves the development of real-time spoken language understanding using the "looking-while-listening" task in typically-developing and at-risk children. Dr. Marchman's current studies explore links between children's language processing skill, early learning environments, and individual differences in monolingual and bilingual English-Spanish learners from diverse backgrounds.

"The language chapter in this new edition again delivers an overview of the many puzzles that characterize the field of language development that is both comprehensive and nuanced. Importantly, the material is grounded in traditional issues that are at the core of key debates that form the foundation of the field. At the same time, the chapter captures new developments in both methodology and theory that reflect how the field has changed over the years. It is especially important that the material is grounded in the real world in ways that link the field of language development to students' own personal and professional lives."
–Virginia Marchman, Stanford University
(photo): Courtesy of Craig T. Salling

Germine Awad Dr. Germine Awad is an Associate Professor in the Department of Educational Psychology at the University of Texas at Austin. Dr. Awad's scholarship is characterized by three interrelated areas of inquiry: prejudice and discrimination, identity and acculturation, and more recently, body image among women of color. She has also written in the area of multicultural research methodology. The majority of her research is guided by the questions "*What factors lead to discrimination against ethnic minorities?*" and "*What impacts perceptions of experienced discrimination?*" The two populations that she has primarily focused on are Arab/Middle Eastern Americans and African Americans. Although overt discrimination towards ethnic minorities has decreased over the years, the practice of more covert, subtle forms of prejudice remains. The events of September 11, 2001, however, reintroduced more explicit forms of prejudice towards Arab/Middle Eastern Americans, and those perceived to be Muslim, complicating the dialogue on discrimination in the United States. Dr. Awad is concerned with how prejudicial attitudes and ideology impact attitudes towards ethnic minorities generally and within specific domains such as the workplace and higher education. In addition, she examines how racial/ethnic identity and acculturation impact ethnic minorities' perception of discrimination. Most recently, she has expanded her identity and acculturation research to the study of body image concerns among women of color.
(photo): Courtesy of Germine Awad

Kevin Cokley Dr. Kevin Cokley holds the Oscar and Anne Mauzy Regents Professorship for Educational Research and Development in the College of Education at the University of Texas at Austin. He is a Fellow of the University of Texas System and University of Texas Academy of Distinguished Teachers, Director of the Institute for Urban Policy Research & Analysis, and Professor of Educational Psychology and African and African Diaspora Studies. His research and teaching can be broadly categorized in the area of African American psychology, with a focus on racial identity and understanding the psychological and environmental factors that impact African American students' academic achievement. Dr. Cokley studies the psychosocial experiences of African American students and students of color and is currently exploring the impostor phenomenon and its relationship to mental health and academic outcomes. He was elected to Fellow status in the American Psychological Association for his contributions to ethnic minority psychology and counseling psychology. He is the recipient of the Charles and Shirley Thomas Award for mentoring ethnic minority students. He holds the title of Distinguished Psychologist and received the Scholarship Award from the Association of Black Psychologists.
(photo): Courtesy of Kevin Cokley

Sabra Katz-Wise Dr. Sabra L. Katz-Wise is an Assistant Professor in Adolescent/Young Adult Medicine at Boston Children's Hospital (BCH), in Pediatrics at Harvard Medical School (HMS), and in Social and Behavioral Sciences at the Harvard T. H. Chan School of Public Health. She also co-directs the Harvard SOGIE (Sexual Orientation Gender Identity and Expression) Health Equity Research Collaborative and she is a Senior Faculty Advisor for the BCH Office of Health Equity and Inclusion. Dr. Katz-Wise's research investigates sexual orientation and gender identity development, sexual fluidity, health inequities related to sexual orientation and gender identity in adolescents and young adults, and psychosocial functioning in families with transgender youth. She is currently working on an NIH-funded community-based study to develop an intervention to support families with transgender youth. In addition to research, Dr. Katz-Wise is involved with advocacy efforts at BCH to improve the workplace climate and patient care for LGBTQ individuals, including her leadership role on the Queer Council for the BCH Rainbow Alliance Diversity and member of the BCH Equity, Diversity, and Inclusion Council. She also serves on the HMS LGBT Advisory Committee and is a Faculty Fellow in the HMS Sexual and Gender Minority Health Equity Initiative.

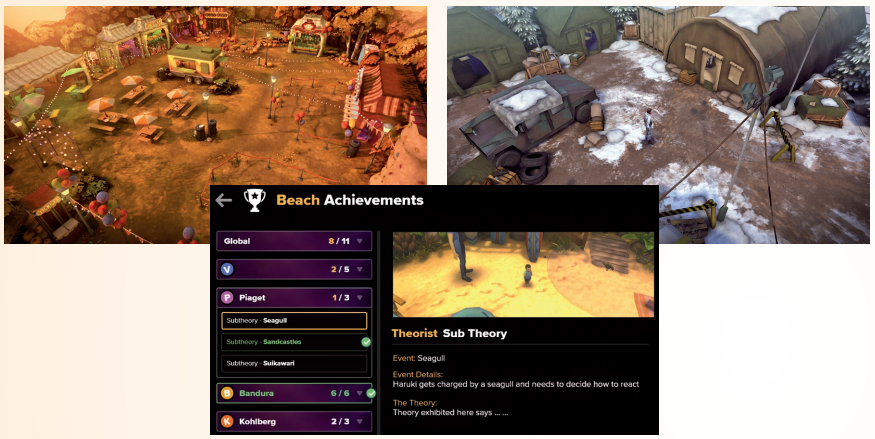
Connecting *Research* and *Results*

As a master teacher, John Santrock connects current research and real-world applications. Through an integrated, personalized digital learning program, students gain the insight they need to study smarter and improve performance.

McGraw Hill Connect is a digital assignment and assessment platform that strengthens the link between faculty, students, and coursework, helping everyone accomplish more in less time. *Connect Psychology* includes assignable and assessable videos, quizzes, exercises, and interactivities, all associated with learning objectives. Interactive assignments and videos allow students to experience and apply their understanding of psychology to the world with fun and stimulating activities.



Apply Concepts and Theory in an Experiential Learning Environment

An engaging and innovative learning game, **Quest: Journey Through the Lifespan**® provides students with opportunities to apply content from their human development curriculum to real-life scenarios. Students play unique characters who range in age and make decisions that apply key concepts and theories for each age as they negotiate events in an array of authentic environments. Additionally, as students analyze real-world behaviors and contexts, they are exposed to different cultures and intersecting biological, cognitive, and socioemotional processes. Each quest has layered replayability, allowing students to make new choices each time they play—or offering different students in the same class different experiences. Fresh possibilities and outcomes shine light on the complexity of and variations in real human development. This new experiential learning game includes follow-up questions, assignable in Connect and auto-graded, to reach a higher level of critical thinking.

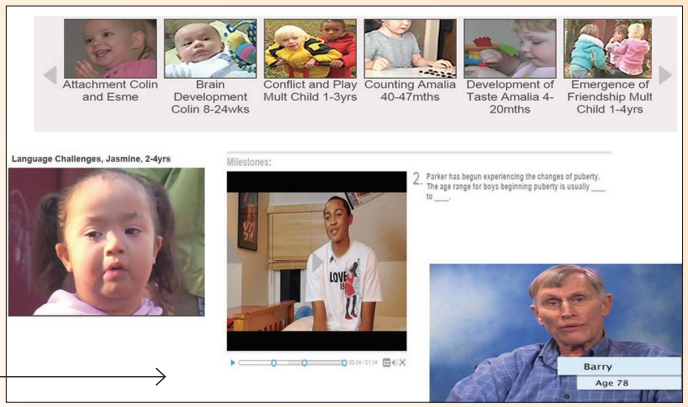
Diversity, Equity, and Inclusion

Substantial discussion in this edition is devoted to addressing issues of diversity, equity, and inclusion. When relevant, each chapter includes citations of studies and topical coverage that represent diverse U.S. and global populations. A complete listing of diversity, equity, and inclusion coverage can be found on pages xi–xvii.

In addition, each chapter includes a *Connecting with Research* feature, many of which highlight underrepresented researchers or research topics to reflect the diversity of the human experience. For example, the *Connecting with Research* interlude in the chapter on language development features Dr. Poorna Kushalnagar and her study on the effects of communication difficulties between hearing parents and deaf children.

Real People, Real World, Real Life

At the higher end of Bloom's taxonomy (analyze, evaluate, create), the **McGraw Hill Milestones** video series is an observational tool that allows students to experience life as it unfolds, from infancy to late adulthood. This groundbreaking, longitudinal video series tracks the development of real children as they progress through the early stages of physical, social, and emotional development in their first few weeks, months, and years of life. Assignable and assessable within Connect Psychology, Milestones also includes interviews with adolescents and adults to reflect development throughout the entire life span. New to this edition, Milestones are available in a more engaging, WCAG-compliant format. Ask your McGraw Hill representative about this new upgrade!



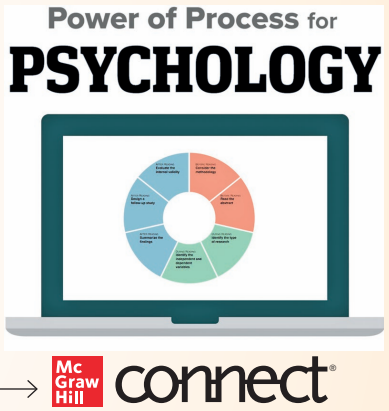
Attachment Colin and Esme
Brain Development Colin 8-24wks
Conflict and Play Mult Child 1-3yrs
Counting Amalia 40-47mths
Development of Taste Amalia 4-20mths
Emergence of Friendship Mult Child 1-4yrs
Language Challenges, Jasmine, 2-4yrs
Milestones:
2. Parker has begun experiencing the changes of puberty. The age range for boys beginning puberty is usually ___ to ___.
Barry
Age 78

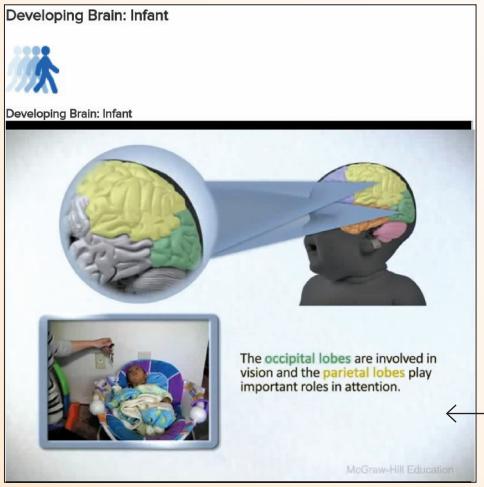
Develop Effective Responses

McGraw Hill's new **Writing Assignment Plus** tool delivers a learning experience that improves students' written communication skills and conceptual understanding with every assignment. Assign, monitor, and provide feedback on writing more efficiently and grade assignments within McGraw Hill Connect. Writing Assignment Plus gives you time-saving tools with a just-in-time basic writing and originality checker.

Prepare Students for Higher-Level Thinking

Also at the higher end of Bloom's taxonomy, **Power of Process** for Psychology helps students improve critical thinking skills and allows instructors to assess these skills efficiently and effectively in an online environment. Available through Connect, preloaded journal articles are available for instructors to assign. Using a scaffolded framework such as understanding, synthesizing, and analyzing, Power of Process moves students toward higher-level thinking and analysis.





Developing Brain: Infant
Developing Brain: Infant
The occipital lobes are involved in vision and the parietal lobes play important roles in attention.
McGraw-Hill Education

Inform and Engage on Psychological Concepts

At the lower end of Bloom's taxonomy, students are introduced to **Concept Clips**—the dynamic, colorful graphics and stimulating animations that break down some of psychology's most difficult concepts in a step-by-step manner, engaging students and aiding in retention. They are assignable and assessable in Connect or can be used as a jumping-off point in class. Complete with audio narration, Concept Clips focus on topics such as object permanence and conservation, as well as theories and theorists like Bandura's social cognitive theory, Vygotsky's sociocultural theory, and Kuhl's language development theory.

Connect Media Sources to Content

Also at the lower end of Bloom's and located in Connect, **NewsFlash** is a multi-media assignment tool that ties current news stories, TedTalks, blogs, and podcasts to key psychological principles and learning objectives. Students interact with relevant news stories and are assessed on their ability to connect the content to the research findings and course material. NewsFlash is updated twice a year and uses expert sources to cover a wide range of topics, such as emotion, personality, stress, drugs, COVID-19, abilities and disabilities, social justice, stigma, bias, inclusion, gender, LGBTQA+, and many more.

Better Data, Smarter Revision, Improved Results

McGraw Hill's **SmartBook** helps students distinguish the concepts they know from the concepts they don't, while pinpointing the concepts they are about to forget. SmartBook's real-time reports help both students and instructors identify the concepts that require more attention, making study sessions and class time more efficient.

SmartBook is optimized for mobile and tablet use and is accessible for students with disabilities. Content-wise, measurable and observable learning objectives help improve student outcomes. SmartBook personalizes learning to individual student needs, continually adapting to pinpoint knowledge gaps and focus learning on topics that need the most attention. Study time is more productive and, as a result, students are better prepared for class and coursework. For instructors, SmartBook tracks student progress and provides insights that can help guide teaching strategies.

Online Instructor Resources

The resources listed here accompany *A Topical Approach to Life-Span Development,* Eleventh Edition. Please contact your McGraw Hill representative for details concerning the availability of these and other valuable materials that can help you design and enhance your course.

Instructor's Manual Broken down by chapter, this resource provides chapter outlines, suggested lecture topics, classroom activities and demonstrations, suggested student research projects, essay questions, and critical thinking questions.

Test Bank and Test Builder This comprehensive Test Bank includes more than 1,500 multiple-choice, short answer, and essay questions. Organized by chapter, the questions are designed to test factual, applied, and conceptual knowledge. New to this edition and available within Connect, Test Builder is a cloud-based tool that enables instructors to format tests that can be printed and administered within a Learning Management System. Test Builder offers a modern, streamlined interface for easy content configuration that matches course needs without requiring a download. Test Builder enables instructors to:

- Access all test bank content from a particular title
- Easily pinpoint the most relevant content through robust filtering options
- Manipulate the order of questions or scramble questions and/or answers
- Pin questions to a specific location within a test
- Determine your preferred treatment of algorithmic questions
- Choose the layout and spacing
- Add instructions and configure default settings

PowerPoint Slides The PowerPoint presentations, now WCAG compliant, highlight the key points of the chapter and include supporting visuals. All of the slides can be modified to meet individual needs.

Remote Proctoring New remote proctoring and browser-locking capabilities are seamlessly integrated within Connect to offer more control over the integrity of online assessments. Instructors can enable security options that restrict browser activity, monitor student behavior, and verify the identity of each student. Instant and detailed reporting gives instructors an at-a-glance view of potential concerns, thereby avoiding personal bias and supporting evidence-based claims.

preface

Making Connections . . . From My Classroom to *A Topical Approach to Life-Span Development* to You

Having taught life-span development for three decades now, I'm always looking for ways to improve my course and *A Topical Approach to Life-Span Development*. Just as McGraw Hill looks to those who teach the life-span development course for input, I ask the approximately 225 students in my life-span development course to tell me what they like about the course and the text, and what they think could be improved. What have my students told me about my course and text? Students said that highlighting connections among the different aspects of life-span development would help them to better understand the concepts. As I thought about this, it became clear that a *connections* theme would provide a systematic, integrative approach to the course material. I used this theme to shape my goals for my life-span development course, which, in turn, I incorporated into *A Topical Approach to Life-Span Development:*

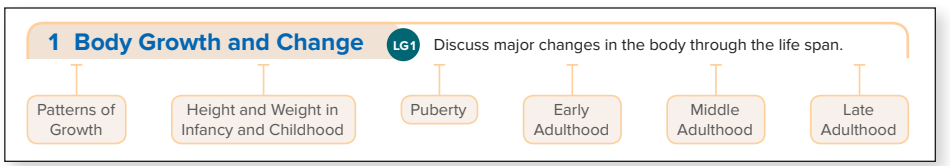
1. **Connecting with today's students** To help students learn about life-span development more effectively.
2. **Connecting research to what we know about development** To provide students with the best and most recent theory and research in the world today about each of the periods of the human life span.
3. **Connecting topical processes in development** To guide students in making *topical connections* across different aspects of development through the life span.
4. **Connecting development to the real world** To help students understand ways to *apply* content about the human life span to the real world and improve people's lives; and to motivate them to think deeply about *their own personal journey through life* and better understand who they were, are, and will be.

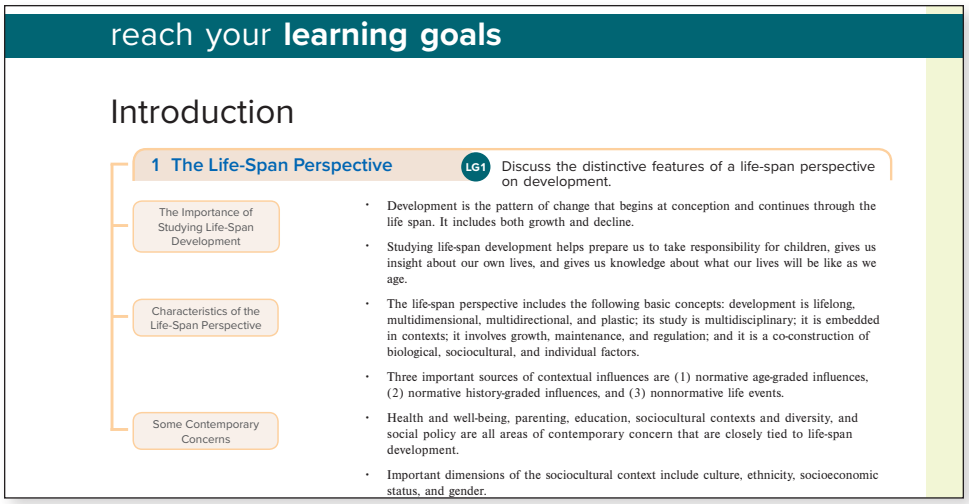
Connecting with Today's Students

In *A Topical Approach to Life-Span Development,* I recognize that today's students are as different in some ways from the learners of the last generation as today's discipline of life-span development is different from the field 30 years ago. Students learn in multiple modalities; rather than sitting down and reading traditional printed chapters in linear fashion from beginning to end, their work preferences tend to be more visual and more interactive, and their reading and study often occur in short bursts. For many students, a traditionally formatted printed textbook is no longer enough when they have instant, 24/7 access to news and information from around the globe. Two features that specifically support today's students are the adaptive ebook, Smartbook (see page xxiv) and the learning goals system.

The Learning Goals System

My students often report that the life-span development course is challenging because of the amount of material covered. To help today's students focus on the key ideas, the Learning Goals System I developed for *A Topical Approach to Life-Span Development* provides extensive learning connections throughout the chapters. The learning system connects the chapter opening outline, learning goals for the chapter, mini-chapter maps that open each main section of the chapter,





reach your **learning goals**

Introduction

1 The Life-Span Perspective — LG1 Discuss the distinctive features of a life-span perspective on development.

The Importance of Studying Life-Span Development

- Development is the pattern of change that begins at conception and continues through the life span. It includes both growth and decline.
- Studying life-span development helps prepare us to take responsibility for children, gives us insight about our own lives, and gives us knowledge about what our lives will be like as we age.

Characteristics of the Life-Span Perspective

- The life-span perspective includes the following basic concepts: development is lifelong, multidimensional, multidirectional, and plastic; its study is multidisciplinary; it is embedded in contexts; it involves growth, maintenance, and regulation; and it is a co-construction of biological, sociocultural, and individual factors.
- Three important sources of contextual influences are (1) normative age-graded influences, (2) normative history-graded influences, and (3) nonnormative life events.

Some Contemporary Concerns

- Health and well-being, parenting, education, sociocultural contexts and diversity, and social policy are all areas of contemporary concern that are closely tied to life-span development.
- Important dimensions of the sociocultural context include culture, ethnicity, socioeconomic status, and gender.

Review, Connect, Reflect questions at the end of each main section, and the chapter summary at the end of each chapter.

The learning system keeps the key ideas in front of the student from the beginning to the end of the chapter. The main headings of each chapter correspond to the learning goals that are presented in the chapter-opening spread. Mini-chapter maps that link up with the learning goals are presented at the beginning of each major section in the chapter.

Then, at the end of each main section of a chapter, the learning goal is repeated in *Review, Connect, Reflect,* which prompts students to review the key topics in the section, connect to existing knowledge, and relate what they learned to their own personal journey through life. *Reach Your Learning Goals,* at the end of the chapter, guides students through the bulleted chapter review, connecting with the chapter outline/learning goals at the beginning of the chapter and the *Review, Connect, Reflect* questions at the end of major chapter sections.

Connecting Research to What We Know about Development

Over the years, it has been important for me to include the most up-to-date research available. I continue that tradition in this edition by looking closely at specific areas of research, involving experts in related fields, and updating research throughout. ***Connecting with Research*** describes a study or program to illustrate how research in life-span development is conducted and how it influences our understanding of the discipline. This edition includes a number of new issues that highlight a more diverse group of researchers and topics, such as "How do parent and peer relationships influence Latinx adolescents' prosocial behavior?" and "Is an individual's personality profile linked to their diversity orientation and attitudes about diversity?" A complete list of related topics can be found in the "Guide to Diversity, Equity, and Inclusion on pages xi to xvii.

connecting with research

Do Parental Expectations Influence Black Boys' Math Scores?

Courtesy Lawrence Jackson

Lawrence Jackson
Key Points:
- Black male adolescents
- parental expectations
- math skills

Researcher Lawrence Jackson, who strives to be an inspiration to other Black boys/men, found extra motivation to pursue a career in psychology from his observations that there were few Black researchers at national conventions (Gradworld FSU, 2019). His research explores the factors that influence young Black boys' academic achievement. In one study, he explored the associations among what Black high school students expected of themselves regarding educational achievement, what their parents expected of them, and the student's performance on a math test (Jackson & others, 2020).

The data for the research came from the large-scale High School Longitudinal study sponsored by the National Center for Education Statistics. Among the 23,000 students from 944 high schools who participated in the study, the focus was on Black boys in ninth grade, resulting in 1,282 participants for this particular analysis. A standardized test of algebraic skills was used as a measure of current academic performance. Also, students' and parents' expectations for the future educational attainment of the student were assessed. Both the parents and students were asked the following question: "How far in school do you think he/you will get?" The response options were:

How do parents' and adolescents' educational expectations influence their education?
Digital Vision/Getty Images

- 8 = Complete master's degree
- 9 = Start professional degree
- 10 = Complete professional degree

The findings indicated that the parents' educational expectations for their children were slightly higher than what their children expected. Most parents responded between 2.64 and 9.2, with their average score at 5.92. Placed in context of the responses to the expectation question, this reveals that most parents expected their child to complete high school, and on average they basically expected the completion of a bachelor's degree. Most of the Black boys responded between 1.54 and 8.88, with their average score of 5.21. This reveals that the students were less certain than their parents that they would complete high school or attain a bachelor's degree.

The tradition of obtaining detailed, extensive input from a number of leading experts in different areas of life-span development also continues in this edition. Biographies and photographs of the leading experts in the field of life-span development appear on pages xix to xxi. Additionally, McGraw Hill's new Board of Advisors for Diversity, Equity, and Inclusion played a pivotal role in suggesting many of the updates for this new edition. Finally, the research discussions have been updated in every area and topic. I expended every effort to make this edition of *A Topical Approach to Life-Span Development* as contemporary and up-to-date as possible. To that end, there are more than 1,500 citations from 2019, 2020, 2021, and 2022. Chapter-by-chapter highlights of new research content are listed on pages xxix–lvi.

Connecting Developmental Processes

Too often we forget or fail to notice the many connections from one point or topic in development to another. ***Developmental Connections,*** which appear multiple times in each chapter, point readers to where the topic is discussed in a previous or subsequent chapter. *Developmental Connections* highlight links across topics and age periods of development *and* connections between biological, cognitive, and socioemotional processes. These key developmental processes are typically discussed in isolation from each other, and students often fail to see their connections. Included in the *Developmental Connections* is a brief description of the backward or forward connection.

Also, a *Connect* question appears in the section self-reviews—*Review, Connect, Reflect*—so students can practice making connections between topics. For example, students are asked to connect a chapter's discussion of the gender-intensification hypothesis to what they have already read about identity development in adolescence.

developmental **connection**

Brain Development

Developmental changes in the adolescent's brain may be related to increased risk taking. Connect to "Physical Development and Biological Aging."

Connecting Development to the Real World

In addition to helping students make research and developmental connections, *A Topical Approach to Life-Span Development* shows the important connections between the concepts discussed and the real world. In recent years, students in my life-span development course have increasingly told me that they want more of this type of information. In this edition, real-life connections are explicitly made through *Connecting Development to Life,* the *Milestones* program that helps students watch life as it unfolds, and *Connecting with Careers*.

Connecting Development to Life, along with a variety of life-span connecting boxed features, describes the influence of development in a real-world context on topics including *Helping Overweight Children Lose Weight*, *Working During College*, and *Communicating with a Dying Person*.

The ***Milestones*** program, described on page xxiii, shows students what developmental concepts look like by letting them watch actual humans develop. Starting from infancy, students track several individuals, seeing them achieve major developmental milestones, both physically and cognitively. Clips continue through adolescence and adulthood, capturing attitudes toward issues such as family, sexuality, and death and dying.

Connecting with Careers profiles careers ranging from an educational psychologist to a toy designer to a marriage and family therapist to a teacher of English language learners to a home

connecting development to life

Are Social Media an Amplification Tool for Adolescent Egocentrism?

Earlier generations of adolescents did not have social media to connect with large numbers of people; instead, they connected with fewer people, either in person or via telephone. Might today's teens be drawn to social media and its virtually unlimited friend base to express their imaginary audience and sense of uniqueness? A research analysis concluded that amassing a large number of friends (audience) may help to validate adolescents' perception that their life is on stage and everyone is watching them (Psychster Inc, 2010). A look at a teen's home Twitter® comments may suggest to many adults that what teens are reporting is often rather mundane and uninteresting as they update to the world at large what they are doing and having, such as: "Studying heavy. Not happy tonight." or "At Starbucks with Jesse. Lattes are great." Possibly for adolescents, though, such tweets are not trivial but rather an expression of the personal fable's sense of uniqueness (Psychster Inc, 2010).

One study of social networking sites found that the indiscriminate monologue communication from one to many, in which the diverse interests of others are not considered, that often occurs on such sites as Facebook® may produce an egocentric tendency that undermines prosocial behavior (Chiou, Chen, & Liao, 2014).

A recent meta-analysis concluded that a greater use of social networking sites was linked to a higher level of narcissism (Gnambs & Appel, 2018).

In what ways might frequent use of social media, such as Facebook®, influence adolescents' cognitive development?
Andrey_Popov/Shutterstock

connecting with careers

Ahou Vaziri, Teach for America Instructor

Ahou Vaziri was a top student in author John Santrock's educational psychology course at the University of Texas at Dallas where she majored in Psychology and Child Development. The following year she served as a teaching intern for the educational psychology course, then applied to Teach for America and was accepted. Vaziri was assigned to work in a low-income area of Tulsa, Oklahoma, where she taught English to seventh- and eighth-graders. In her words, "The years I spent in the classroom for Teach for America were among the most rewarding experiences I have had thus far in my career. I was able to go home every night after work knowing that I truly made a difference in the lives of my students."

After her two-year teaching experience with Teach for America, Vaziri continued to work for the organization in their recruitment of college students to become Teach for America instructors. Subsequently, she moved into a role that involved developing curricula for Teach for America. Recently she earned a graduate degree in counseling from Southern Methodist University and currently is pursuing her doctoral degree in counseling psychology at the University of North Texas. During her graduate studies, she is continuing to work toward improving children's lives.

Ahou Vaziri with her students in the Teach for America program. *What is Teach for America?*
Courtesy of Ahou Vaziri

hospice nurse, each of which requires knowledge about human development.

A number of new profiles appear in this and recent editions. These include Gustavo Medrano, a clinical psychologist who works at the Family Institute at Northwestern University, especially providing therapy for Latinx children; Dr. Bonnie Halpern-Felsher, a university pediatrics professor and director of community efforts to improve adolescents' health; Dr. Melissa Jackson, a child and adolescent psychiatrist who provides therapy for children with a number of psychological disorders, including ADHD, anxiety, depression, and post-traumatic stress disorder; Carissa Barnes, a special education teacher; and Ahou Vaziri, a Teach for America instructor and curriculum designer.

The careers highlighted extend from the Careers Appendix that provides a comprehensive overview of careers in life-span development to show students where knowledge of human development could lead them.

Part of applying development to the real world is understanding its impact on oneself. An important goal I have established for my life-span development course and this text is to motivate students to think deeply about their own journey of life. To further encourage students to make personal connections to content in the text, *Reflect: Your Own Personal Journey of Life* appears in the end-of-section review in each chapter. This feature involves a question that asks students to reflect on some aspect of the discussion in the section they have just read and connect it to their own life. For example, students are asked:

Imagine what your development would have been like in a culture that offered fewer or distinctly different choices. How might your development have been different if your family had been significantly richer or poorer than it was when you were growing up?

In addition, students are asked a number of personal connections questions in the photograph captions.

Content Revisions

A significant reason why *A Topical Approach to Life-Span Development* has been successfully used by instructors for edition after edition is the painstaking effort and review that goes into making sure the text provides the latest research on all topic areas discussed in the classroom. This new edition is no exception, with more than 1,500 citations from 2019, 2020, 2021, and 2022.

This new edition is being released at a time when the world is well over a year into the COVID-19 pandemic health crisis, as more and more people are getting vaccinated and parts of the world are slowly returning to pre-pandemic status while other areas are still battling the raging virus. We are already seeing a great deal of research in many related topics, which are mentioned throughout this edition. Additionally, a new main section "Schools and the Coronavirus Pandemic" has been added on how K-12 and college education had to be quickly redesigned to address this challenge and some of the immediate outcomes.

Also since the last edition published, a number of events have occurred that have exposed the results of discrimination, systemic racism, and intolerance in the United States and throughout the world. *A Topical Approach to Life-Span Development* has historically covered these important issues and related research and, beyond many significant updates, this edition also includes a number of new *Connecting with Research* interludes that highlight researchers and their research in the areas of diversity, equity, and inclusion. Additionally, related topics can be easily found by using the "Guide to Diversity, Equity, and Inclusion" on pages xi to xvii.

Following is a sample of the many chapter-by-chapter changes that were made in this new edition of *A Topical Approach to Life-Span Development*.

Chapter 1: Introduction

- New commentary about how projected increases in the older population in countries around the world will require countries to develop innovative policies and expanded services for housing, employment, health care, and transportation (Carstensen, 2015, 2019)
- Updated data on life expectancy in the United States (Arias & Xu, 2019)
- New description of how in 2019, for the first time in U.S. history, there were more individuals over the age of 60 than under the age of 18
- Coverage of very recent projections for a decline of approximately one year in the average U.S. life expectancy in 2020, with a three- to four-year drop for African Americans and Latinxs because of the staggering number of deaths during the COVID-19 pandemic (Andrasfay & Goldman, 2021)
- Inclusion of new content on how the COVID-19 pandemic has disproportionately harmed older adults, making them more vulnerable to contracting a severe or deadly version of the disease, as well as uprooting their lives by isolating them from family and friends (Jowell, Carstensen, and Barry, 2020)
- Updated poverty rates that dropped considerably from 2018 to 2019 for African American, Latinx, and Asian American children and adolescents, including a much larger drop than for non-Latinx White children and adolescents (Semega & others, 2020)
- Coverage of a recent research review of 3- to 19-year-old U.S. children and adolescents indicating that those living in low-socioeconomic-status (SES) settings were likely to have higher levels of psychopathology (Peverill & others, 2021)
- Inclusion of a recent focus of the Ascend two-generation program on the importance of parents' education, economic stability, and overall health for their children's well-being (Ascend, 2021; Aspen Institute, 2019)
- Description of a recent research study that found older adults who were more conscientious and emotionally stable were less cognitively vulnerable (Duchek & others, 2020)
- Coverage of a recent study revealing that at 65 years of age, individuals' happy life expectancy was 25 percent more than their cognitive impairment life expectancy, and at age 85 their happy life expectancy doubled to 50 percent greater than their cognitive impairment life expectancy (Bardo & Lynch, 2021)
- Inclusion of research data collected in April 2020 from 18- to 76-year-olds in which older adults reported more frequent positive emotions and less frequent and intense negative emotions than younger adults, despite being more aware of the risks posed to them by the COVID-19 pandemic (Carstensen, Shavitz, & Barnes, 2020)
- Discussion of recent research across 150 countries indicating that health is a better predictor of life satisfaction in individuals 58 years and older than in younger age groups (Joshanloo & Jovanovic, 2021)
- Important new section, "Are Age Ranges for Adult Periods of Development Changing?"
- New section, "Age Range for Middle Age," that focuses on a changing middle age that appears to be beginning later and lasting longer for an increasing number of people
- Description of a recent study of 44- to 64-year-olds who reported feeling younger than they actually were and wanting to be younger than their chronological age (Shinan-Altman & Werner, 2019). In this study, participants said that old age doesn't begin until 69 years of age.
- New section "Changing Late Adulthood," noting that older adults constitute an increasing percentage of the total population as fertility rates decrease and improving lifestyles and medical discoveries are increasing life expectancy (Freund, 2020; Staudinger, 2020)
- Inclusion of recent research indicating that an adult's biological age was a good predictor of whether they would have a stroke recurrence (Soriano-Tarraga & others, 2021)
- Expanded and updated information on the use of eye-tracking to assess cognitive exploration (D'Souza & others, 2020) and language acquisition in infants (Egger, Rowland, & Bergmann, 2020)

Chapter 2: Biological Beginnings

- Updated and revised content based on feedback from leading experts David Moore and Charles Nelson
- Expanded criticism of evolutionary psychology indicating that it is very difficult to offer direct proof of an argument to support this view
- Updated content on genome-wide association studies of obesity (Warner & others, 2021), depression (Wu & others, 2021), autism (Searles Quick, Wang, & State, 2021), and Alzheimer disease (Serrano-Pozo, Das, & Hyman, 2021)
- Updated and expanded coverage of gene linkage analysis to include its use in studying cancer (Wang & others, 2021), bipolar disorder (Umehara & others, 2021), suicide (Sokolowski & Wasserman, 2020), and glaucoma (Trivli & others, 2020)
- Expansion of gene expression discussion to include loneliness (Brown & others, 2020)
- Updated and expanded research on how diet (Ramos-Lopez & others, 2021), tobacco use (Sugden & others, 2019), and sleep (Lehtinen & others, 2019) can modify the expression of genes through the process of methylation
- Inclusion of recent research indicating that methylation is involved in stress (Gatta & others, 2021), hypertension (Amenyah & others, 2021), colorectal cancer (Alvizo-Rodriguez & others, 2020), breast cancer (Xu & others, 2020), leukemia (Kingsley & others, 2020), obesity (Gomez-Alonso & others, 2021), depression (Lapato & others, 2021), and attention deficit hyperactivity disorder (Kim & others, 2020)
- Updated and expanded coverage of susceptibility genes, including those involved in COVID-19 (Sang & others, 2021), arthritis (Reynard & Barter, 2020), colorectal cancer (Yuan & others, 2021), cardiovascular disease (Liang & others, 2020), and Parkinson disease (Langmyhr & others, 2021)
- Coverage of recent researching indicating that *FOXO3A* may serve as a novel blood marker for early detection of Alzheimer disease (Pradhan & others, 2020)
- Updated and expanded research on gene-gene interaction to include immune system functioning (Kostel Bal & others, 2020), cancer (Lee & others, 2021), and obesity (Jung & others, 2020)
- Inclusion of a recent study that found while XYY boys did not have more cognitive deficits than normal XY boys, they did have more externalizing and internalizing problems (Operto & others, 2019)
- New content on the number of children born worldwide with sickle-cell anemia and how stem cell transplantation is being explored in the treatment of infants with sickle-cell anemia (Cisneros & Thein, 2020)
- Coverage of a recent research review concluding that variations in the 5-HTTPLR gene may contribute to the tendency to ruminate when individuals face life stress (Scaini & others, 2021)
- Discussion of three recent studies indicating that the short version of the 5-HTTPLR gene is linked to greater risk of depression in individuals with coronary heart disease (Zhang & others, 2020), stroke (Wang & others, 2020), and Parkinson disease (Cheng & others, 2020)
- New commentary about neurogenesis being largely complete by about the end of the fifth month of prenatal development (Borsani & others, 2019)
- Description of a recent global analysis that concluded mandatory folic acid fortification of flour or wheat was reaching only 23 percent of total possible prevention (Kancherla & others, 2021)
- New coverage of cell-free fetal DNA in maternal blood and its testing as early as 10 weeks into the first trimester of pregnancy to identify disorders such as Down syndrome (Guseh, 2020)
- Inclusion of a recent study using non-invasive fetal diagnosis that revealed fetal sex at 4.5 weeks (D'Aversa & others, 2018)
- Coverage of a recent review of 17 meta-analyses that concluded maternal caffeine consumption during pregnancy was linked to a higher occurrence of miscarriage, stillbirth, low birth weight, and childhood acute leukemia (James, 2021)
- Description of a recent meta-analysis that found higher maternal caffeine intake during pregnancy was associated with childhood overweight and obesity (Jin & Qiao, 2021)
- Inclusion of recent research in which children with FASD had impairments in verbal comprehension, perceptual-motor coordination, processing speed, attention, executive function, and language development (Lange & others, 2021)
- Discussion of a recent study that confirmed a significant risk for suicidal behavior in adolescents with FASD (O'Connor & others, 2019)
- Inclusion of a recent study that revealed maternal alcohol use during pregnancy was associated with offsprings' mental health problems, such as anxiety, depression, and emotional problems, even at low to moderate levels of consumption (Easey & others, 2019)
- Description of a recent study that found a number of negative cognitive and behavioral outcomes for infants in the first year of life as a consequence of prenatal exposure to cigarette smoke: negative affect, poorer attention, greater excitability, and more irritability (Froggatt, Covey, & Reissland, 2020)
- Coverage of recent research in which maternal cigarette smoking during pregnancy was associated with lower academic achievement in offspring at 16 years of age (Kendler & others, 2021)
- Inclusion of a recent analysis that concluded smoking cessation at any point during pregnancy improved fetal outcomes (American College of Obstetricians and Gynecologists, 2020). Also in this analysis, the greatest benefits for the fetus occurred when the smoking cessation took place prior to 15 weeks of gestation.
- Discussion of a recent study that revealed environmental tobacco smoke during pregnancy was associated with preterm birth (Chen & others, 2021)
- New coverage of a recent study in which chronic exposure to e-cigarette aerosols was linked to low birth weight in offspring (Orzabal & others, 2019)

- Description of a longitudinal study in which prenatal cocaine exposure was linked to early use of marijuana, arrest history, conduct disorder, and emotion regulation problems at 21 years of age (Richardson & others, 2019)
- Discussion of recent research that found newborns born to mothers who used marijuana during pregnancy were more likely to be born preterm or low birth weight (Haight & others, 2021; Petrangelo & others, 2019)
- Inclusion of a recent study in which marijuana use during pregnancy was associated with an increased rates of chronic obstructive pulmonary disease in 4-year-old children (Villarreal & others, 2019)
- Coverage of recent research indicating that marijuana use during pregnancy is linked to a higher level of psychopathology (internalizing and externalizing problems) and a lower level of gray matter volume in the brains of offspring (Paul & others, 2021)
- Description of a recent study indicating that marijuana use by pregnant women increased from 6 percent to 11 percent in California following its legalization in that state (Lee & others, 2021)
- Inclusion of a recent analysis noting that approximately one-third of women of reproductive age are obese (Moholdt & Hawley, 2020)
- Coverage of a recent study that found obesity in pregnancy was linked to an increased risk of asphyxia-related complications in preterm birth (Mitha & others, 2020)
- Discussion of a recent meta-analysis in which offspring of women who were overweight or obese had an increased risk of developing childhood diabetes and obesity (Hidayat, Zou, & Shi, 2019)
- Description of a recent study that indicated higher maternal pregnancy-related anxiety was linked to more emotional symptoms, peer relationship problems, and overall child difficulties at 4 years of age (Acosta & others, 2020)
- Coverage of a recent study in which individuals whose mothers reported having higher levels of stress during pregnancy were at a higher risk of developing psychiatric disorders, such as mood disorders, later in life (Brannigan & others, 2019)
- Inclusion of recent research in which pregnancy after 35 years of age was associated with diabetes, hypertension, and having a cesarean section (Montori & others, 2021). Also, in this research, after 40 years of age, pregnancy was linked to a higher risk for fetal death, neonatal ICU admission, and postpartum hemorrhage (Montori & others, 2021)
- Description of a recent study that revealed daily e-cigarette smokers had a lower sperm count than non-users (Holmboe & others, 2020)
- Discussion of a recent meta-analysis that concluded paternal smoking before and during pregnancy was linked to increased risk of childhood leukemia (Cao, Lu, & Lu, 2020)
- Coverage of recent research that revealed the mother's perceived stress during pregnancy was elevated when the father was physically and verbally aggressive toward her (Kashanian & others, 2021). Also, her stress was lower when the father was emotionally and financially supportive and when he participated in prenatal care visits.
- Inclusion of a recent study in which African American and Latinx women reported almost twice as many barriers to prenatal care as non-Latinx White women (Fryer & others, 2021)
- Discussion of a recent large-scale study that found women who participated in CenteringPregnancy had offspring that were less likely to be born preterm or low birth weight (Cunningham & others, 2019)
- Inclusion of recent research that indicated women who participated in CenteringPregnancy used pain relief less during labor and were more likely to breast feed their infants (Rijnders & others, 2019)
- Description of a recent study in which yoga was effective in reducing depressive symptoms in pregnant women (Ng & others, 2019)
- Coverage of a recent research review that concluded pregnant women's exercise was linked to a lower incidence of preterm birth (Mate & others, 2020)
- New content on ethnic disparities in prenatal care and pregnancy, with African American and Native American/Alaska Native women especially experiencing inadequate care (Petersen & others, 2019)
- Updated data on the percentage of births taking place in different settings, with the largest percentage increase occurring in homes (MacDorman & Leclerq, 2019)
- Updated data on the percentage of U.S. births attended by a midwife, which increased to 9.1 percent in 2017 (Center for Health Statistics, 2019)
- Update on the percentage of U.S. births that were cesarean deliveries (31.9 percent in 2018) (Martin & others, 2019)
- Coverage of a recent study in which one hour of traditional Thai massage decreased the duration of the first and second stages of labor (Sananpanichkul & others, 2019)
- Description of a recent study of 27,000 women in which those using waterbirth had more favorable outcomes for themselves and that their newborns were less likely to be placed in a NICU or to have heart rate abnormalities and respiratory complications (Snapp & others, 2020)
- Discussion of a recent research review in which women who used waterbirth perceived it to be a positive experience (Feeley, Cooper, & Burns, 2021)
- Inclusion of a recent study that indicated Apgar scores at 5 and 10 minutes after birth provide prognostic information about preterm infants' ability to survive (Cnattingius, Johansson, & Razaz, 2020)
- Updated data on the percentage of U.S. infants who are born preterm, including ethnic variations (Martin & others, 2019)
- Updated data on the percentage of U.S. babies born at low birth weights, including ethnic variations (Martin & others, 2019)
- Description of a recent Japanese study of very low birth weight infants that found 6.2 percent had birth defects, with the most common being chromosomal abnormalities, heart defects, and malformation of the digestive system (Kawasaki & others, 2021)

- Inclusion of a recent national study of 6- to 11-year-old children in which those born preterm had higher rates of developmental delay, intellectual disability, speech/language disorder, learning disability, and ADHD (Kelly & Li, 2019)
- Discussion of a recent study that revealed lower academic trajectories for very preterm born children in elementary school (Twilhaar & others, 2019)
- Description of a recent research review of preterm and low birth weight infants that found those who received maternal kangaroo care for at 2 to 6 hours a day gained more weight than those who did not get the care (Charpak, Montealegre-Pomar, & Bohorquez, 2021). However, the weight gain effect disappeared when infants received only 2 hours or less per day of this care.
- Coverage of a recent large-scale experimental study in India in which low birth weight infants were randomly assigned to receive kangaroo care or standard care, with the low birth weight infants who received kangaroo care having higher survival rates in the first month of life as well as 180 days later (Mazunder & others, 2019)
- Inclusion of recent research with preterm infants that found those who received massage therapy had a significant daily weight gain and an increase in bone mineral density (Elmoneim & others, 2021)
- Coverage of recent research showing that in the postpartum period, women who engage in light-to-moderate physical activity are less likely to experience poor sleep quality (Matenchuk & Davenport, 2021)
- Description of a recent meta-analysis that revealed the prevalence of postpartum depression in fathers was 9 percent in the first month after birth and 8 percent one to three months after birth (Rao & others, 2020)
- Inclusion of recent research in Japan indicating that 11.2 percent of fathers had postpartum depression one month following delivery (Nishigori & others, 2020)

Chapter 3: Physical Development and Biological Aging

- Coverage of a recent meta-analysis that found recombinant growth hormone replacement therapy was effective in eliciting metabolic changes in children with growth hormone deficiency (Yuan & others, 2021)
- Inclusion of a recent study in Taiwan that found the average age of menarche had declined 0.43 years per decade in the past 30 years (Chow & others, 2021)
- Discussion of a recent research review of 30 studies in different countries around the world that revealed the age at which breast development began in girls (called thelarche) declined by almost 3 months per decade from 1977 to 2013 (Eckert-Lind & others, 2020)
- Coverage of a recent study of 11- to 14-year-olds that revealed those who felt negative about their body image because of social media had higher rates of depressive symptoms, online social anxiety, more difficulty in finding friends, and were more socially isolated (Charmaraman & others, 2021). Also in this study, those who followed celebrities checked social media more often and were more likely to have depressive symptoms and online social anxiety.
- Description of a recent study of adolescent boys that indicated a high level of testosterone was linked to less delay of gratification (Laube, Lorenz, & van den Bos, 2019)
- Inclusion of a recent study of early adolescent boys in Japan that found a lower level of testosterone was associated with social withdrawal (Hayashi & others, 2020)
- Discussion of a recent study that revealed age of menarche has declined in recent years in Portugal (Queiroga & others, 2020)
- Coverage of recent research that found obesity was associated with earlier pubertal onset (Busch & others, 2020)
- Description of a recent study of Chinese adolescents that revealed girls were more dissatisfied with their appearance than boys were, but boys were more dissatisfied with their sexual organs (Zhang & others, 2020)
- Inclusion of a recent study of young adolescents in which girls had a more negative body image when they identified with an idealized social media portrayal (Rodgers & others, 2020)
- Coverage of recent research in which higher social media use was linked to more negative body images for adolescents, more so for girls than boys (Kelly & others, 2019)
- Updated content indicating that in 2017–2018, middle-aged adults had a higher obesity rate (44.8 percent) than younger (40.0 percent) and older adults (42.8 percent) (Hales & others, 2020). Also, middle-aged men had a higher obesity rate (46.4 percent) than middle-aged women (43.3 percent) (Hales & others, 2020).
- New commentary noting that for individuals who are 30 percent or more overweight, the probability of dying in middle adulthood increases by 40 percent
- Inclusion of a recent study in which smoking and diabetes were risk factors for accelerated loss of muscle mass in middle-aged women (Lee & Choi, 2019)
- Coverage of a recent meta-analysis that concluded older adults who have sarcopenic obesity are at increased risk of adverse musculoskeletal outcomes such as falls and fractures than individuals with sarcopenia, obesity, or neither condition (Gandham & others, 2021)
- Inclusion of recent research with individuals 55 years of age and younger indicating that those with hypertension had lower scores on a memory test (Teles de Menezes & others, 2021)
- Discussion of a recent study in which most of Life's Simple 7 actions were linked to greater longevity (van Oort & others, 2021)
- Description of a recent study of middle-aged adults that found higher cardiorespiratory fitness predicted lower cardiovascular disease risk (Swainson, Ingle, & Carroll, 2019)
- Discussion of a recent study that revealed lower body mass index, less exercise, frequent alcohol drinking, and a meat-based diet were risk factors for lung cancer in never-smoking women (Ko & others, 2020)
- Coverage of a recent study of more than 300,000 women that found late menopause was associated with an increased risk of breast cancer (Gottschalk & others, 2020)

- Description of recent MRI research documenting the role of both the left and right hemispheres in language development (Bosseler & others, 2021). In this study of 18- to 27-month-olds, attention in the right frontal cortex was important in left-lateralized word learning.
- Discussion of recent research documenting that attention (Bartolomeo & Seidel Malkinson, 2019) and emotion (Gainotti, 2019) are predominantly right hemisphere activities
- Coverage of MRI research demonstrating that both the right and left hemispheres are involved in the control and processing of emotions (Baja & Killgore, 2021)
- Inclusion of some changes in the development of the brain from infancy through the childhood years based on comments by leading experts Charles Nelson and Martha Ann Bell
- New description of aspects of brain activity that can be assessed by the brain imaging technique fNIRS in infancy, including face processing, perception, attention, and memory (Anderson & others, 2020)
- Coverage of a follow-up of children that revealed those who had lived in a Romanian orphanage during their first few years of life but were later placed in stable foster care showed improved brain functioning after being transferred to foster care (Debnath & others, 2020)
- Discussion of a recent study of 9- to 10-year-olds in which children with a high body mass index has less cortical thickness, which was linked to a lower level of executive function (Laurent & others, 2020)
- Inclusion of recent research indicating that emerging cognitive control in children is mainly supported by the development of distributed neural networks in which the prefrontal cortex is central (Chevalier & others, 2019)
- Description of a recent study in which reduced amygdala-prefrontal connectivity occurred in children with autism spectrum disorder (Ibrahim & others, 2019)
- Discussion of recent research with 9- to 23-year-olds in which similar brain aging patterns were found for girls and boys, although the brain changes in girls occurred approximately one year earlier than in boys (Brouwer & others, 2021)
- Coverage of recent research indicating that the corpus callosum continues to thicken well into the third decade of life (Danielsen & others, 2020). In this study, the corpus callosum showed protracted decline in the mid-to-late fifties, followed by further decline in subsequent decades.
- New content on increased connectivity of brain regions at the onset of emerging adulthood and discussion of recent research indicating that connectivity between the frontal cortex and hippocampus increased from adolescence to emerging and early adulthood, with this connectivity linked to improvement in higher-level cognition, especially in problem solving and planning (Calabro & others, 2020)
- Coverage of recent research indicating that brain atrophy occurs less in women than men (Kirov & others, 2021)
- Inclusion of recent research with mice indicating that chronic stress followed by social isolation decreases hippocampal neurogenesis (Du Preez & others, 2021)
- Description of recent research in which sleep-specific brain activity restored performance by actively refining brain plasticity (Nissen & others, 2021)
- Discussion of World Health Organization (WHO) recommendations for how much quality sleep infants 0 to 3 months, 4 to 11 months, and 1 to 2 years of age should get daily (Willumsen & Bull, 2020)
- Inclusion of research information indicating that a lower quality of infant sleep is linked to inconsistent bedtime routines (Covington & others, 2019), maternal depression (Cook & others, 2020), and higher amounts of screen time (Chen & others, 2019)
- Description of a recent research review concluding that the neurotransmitter serotonin plays an important role in SIDS (Cummings & Leiter, 2020)
- Discussion of a study of 732 cases of SIDS that found bed-sharing occurred in 53 percent of the deaths (Drake & others, 2019)
- Coverage of a recent study in which shorter sleep duration in infancy was linked to lower cognitive and language development at 2 years of age (Smithson & others, 2018)
- Inclusion of WHO's recommendation that 3- to 4-year-old children should get 10 to 13 hours of good-quality sleep daily, which may include a nap, with consistent sleep and wake-up times (Willumsen & Bull, 2020)
- Description of a recent study linking quality parenting (harmonious and reciprocal) to preschool children's longer sleep duration (Dubois-Comtois & others, 2019)
- New content linking sleep problems to children's obesity (Poorolajal & others, 2020) and ADHD (Bioulac & others, 2020)
- Updated data indicating that U.S. adolescents are not getting nearly enough sleep, with recent national research showing a 7 percent decline in total sleep time over a period of four years (Kann & others, 2018)
- Discussion of research indicating that frequency of phone calls, mobile phone dependency, and tablet use were linked to sleep problems in adolescence (Cabre-Riera & others, 2019)
- Inclusion of a recent study of college students in which sleep deprivation was linked to a lower grade point average and delayed college graduation (Chen & Chen, 2019)
- Description of a recent study that found poorer sleep quality was associated with smartphone dependence and less effective stress management (Wang & others, 2019)
- Coverage of the National Sleep Foundation's (2020) recommendation that emerging and young adults should get 7 to 9 hours of sleep per night
- New content on the National Sleep Foundation's (2019) explanation of why pulling an all-nighter to cram for an exam is not likely to be a good idea
- New commentary that the National Sleep Association (2020) recommends middle-aged adults get 7 to 9 hours of sleep daily and that older adults get 7 to 8 hours daily
- Inclusion of a recent Norwegian study of individuals 40 years of age and older in which 42 percent of women and 52 percent

of men got less than 7 hours of sleep per night (Sivertsen & others, 2021)

- New description of a recent study of middle-aged adults that indicated lower sleep quality was linked to a lower level of executive function, lower processing speed, increased learning difficulty, and poorer memory recall (Kaur & others, 2019)
- New content on how not only sleeping too little but also sleeping too much can be an indicator of health problems
- Discussion of a recent study that revealed older adults with major depression reported having poor sleep quality (Pye & others, 2021)
- New coverage of how sleep difficulties are increasingly recognized as a risk factor for Alzheimer disease (Andre & others, 2021)
- Inclusion of a recent study of older adults that found a higher frequency and duration of sleep awakenings throughout the night were linked to a increased frailty and shorter longevity (Guida & others, 2021)
- Description of a recent study of individuals 60 years of age and older that revealed for those sleeping 7 hours or less per night, replacing 30 minutes of sedentary activity with 30 minutes of moderate or vigorous physical activity resulted in improved cognitive function (Wei & others, 2021)
- Updated data on life expectancy in the United States (Xu & others, 2020)
- Updated data on gender and ethnic differences in life expectancy in the United States (Murphy & others, 2018; Xu & others, 2020)
- New discussion of the "Latinx Health Paradox," which refers to Latinxs living 3.2 years longer than non-Latinx Whites despite having lower income and less education, including reasons why this may occur (Brill, 2019; Tabler & others, 2020)
- Coverage of a recent study that supported the "Latinx Health Paradox," in which older Latinx adults reported better health than their non-Latinx White counterparts did (Olsen, Basu Roy, & Tseng, 2019)
- Inclusion of recent data on the number (82,000) of centenarians alive in the world (Buchholz, 2020) and a recent (2020) list of the world's oldest living people, including the observation that the 50 oldest individuals were women
- Updated data on life expectancy for individuals 65 years of age (including gender differences) and for individuals 100 years old (Murphy & others, 2018)
- Update as of June 2020 on the oldest living person in the world (Kane Tanaka, 117, in Japan)
- Coverage of a recent research review that concluded lifestyle interventions involving exercise and diet are linked to a slowing of telomere shortening (Qiao & others, 2020)
- Inclusion of a recent study of older adults in which maintaining a healthy body weight was linked to reduced oxidative stress (Anusruti & others, 2020)
- New content indicating that mitochondria play an important role in neuronal plasticity (Lees & others, 2020)
- Expanded and updated content on the role of sirtuins in diabetes, Alzheimer disease, and Parkinson disease (Liu & others, 2020; Shieh & others, 2020)
- Inclusion of new content indicating that SIRT 6 is involved in DNA repair and greater longevity (Das, 2021)
- New content on the emergence of new viral diseases that have severe health consequences and have attacked the immune system function of older adults. The COVID-19 pandemic in 2020 highlights the capacity of viral diseases to decimate the already declining immune system function of older adults (Salimi & Hamlyn, 2020).

Chapter 4: Health

- New commentary that the COVID-19 pandemic caused many parents to postpone taking their children to their physician's office for routine checkups and timely immunizations
- New content on how the COVID-19 pandemic disrupted medical care for children and adolescents
- Inclusion of a recent study in which children and adolescents were 70 percent less likely to visit a general hospital emergency department after the COVID-19 pandemic emerged than before it appeared (Goldman & others, 2021)
- New description of how the COVID-19 pandemic intensified mental health concerns for adolescents (Saggioro de Figueiredo & others, 2021)
- Updated description of the causes of death in childhood, with the leading cause of death in U.S. 1- to 9-year-olds being unintentional injury (Heron, 2019)
- New content indicating that children living in poverty have higher rates of accidents. asthma, and death than children from higher-income families (Kelleher, Reece, & Sandel, 2018)
- New coverage of ethnic disparities in health insurance coverage and chronic health conditions among U.S. children (Carratala & Maxwell, 2020)
- Discussion of a recent national study that found children with a smoker in the home were 30 percent more likely have an asthma diagnosis than children who did not have a smoker in the home (Xie & others, 2021)
- Coverage of a recent study in which young children exposed to environmental tobacco smoke were more likely to have hyperactive and conduct problem symptoms than their counterparts who were not exposed to smoke (Gatzke-Kopp & others, 2019)
- Inclusion of recent research indicating that adolescents with poor-quality friendships during the previous year were more likely to subsequently engage in delinquency (Cho & Galehan, 2020)
- New *Connecting with Careers* profile of Dr. Bonnie Halpern-Felsher, University Professor of Pediatrics and Director of Community Efforts to Improve Adolescents' Health
- Description of a recent study of college students in which regularly eating breakfast was associated with having a higher grade point average (GPA), while regularly eating fast food was linked to having a lower GPA (Reuter, Forster, & Brister, 2020)
- New coverage of ethnic health disparities in U.S. adults 20 years of age and older (Health United States. 2019)

- New content on the large number of older adults who have died because of the coronavirus, with the greatest risk of death for individuals 85 years of age and older (Centers for Disease Control and Prevention, 2020b). Key reasons for increased mortality risk include the fact that older adults are more likely to have underlying health conditions, such as heart disease or kidney disease, and also have a declining immune system that is less effective in fighting the virus.
- Inclusion of a recent Swiss study that found post-menopausal women were consuming large amounts of vegetables but insufficient calcium and dairy products (Lanyan & others, 2020)
- Revised definition of dementia (Alzheimer's Association, 2020)
- Coverage of a recent Chinese study in which medium to high levels of physical activity were linked to a lower incidence of dementia in 60- to 65-year-olds (Wu & others, 2020)
- Updated data on the percentage of older adults with Alzheimer disease and expanded facts about Alzheimer disease in 2020, including new data on ethnic variations (Alzheimer's Association, 2020)
- New description of the ApoE2 allele being the strongest protective gene for Alzheimer disease (Serrano-Pozo, Das, & Hyman, 2021)
- Inclusion of recent research that indicated differences in ApoE4 and ApoE2 alleles were associated with methylation variations in the blood, especially lipid and cholesterol processes (Walker & others, 2021)
- New content on the role of mitochondrial dysfunction as an early event in Alzheimer disease (Yang & others, 2020a)
- Updated estimate on the percentage of individuals 65 years of age and older in the United States who have mild cognitive impairment (Alzheimer's Association, 2020)
- Discussion of a recent research review that concluded cognitive and physical interventions can improve the cognitive and physical function of individuals with mild cognitive impairment (Yang & others, 2020)
- Coverage of the extensive research effort underway to discover drugs that will decrease or remove plaques and tangles in the brain (Zetterberg & Bredlin, 2021)
- New commentary that in the United States 50 percent of the help provided by caregivers for older adults is given to individuals with Alzheimer disease (Alzheimer's Association, 2020)
- New content on the very high percentage of deaths from the coronavirus pandemic that occurred in nursing homes and the accompanying increased concern about the quality of nursing homes in the United States
- Update on breast feeding rates continuing to increase in the United States based on 2017 data (Centers for Disease Control and Prevention, 2020)
- Description of a research review that concluded breast feeding benefits the development of the immune system that provides defenses for fighting off disease (Nolan, Parks, & Good, 2019)
- Discussion of a recent study that revealed breast-fed infants were less likely to develop a fever in the first six months of their lives (Saeed, Haile, & Cherlok, 2020)
- Inclusion of recent research indicating that breast feeding during infancy was associated with increased vegetable intake and avoidance of sugar-sweetened beverages in childhood but not in adolescence (Kheir & others, 2021)
- Coverage of a recent meta-analysis in which breast feeding was linked to a higher level of cardiovascular fitness in children 4 to 18 years old (Berlanga-Macias & others, 2020)
- New discussion of recent conclusions by the American College of Obstetricians and Gynecologists (ACOG) committee (2021) noting that women who breast feed have a reduced risk for breast cancer, ovarian cancer, type 2 diabetes, and hypertensive cardiovascular disease
- Description of a recent national study that found children's dietary quality decreased between 6 months and 4 years of age (Hamner & Moore, 2020)
- Discussion of a recent study that found positive parenting emphasizing praise for healthy eating behavior improved young children's eating behavior and helped them to lose weight better than negative comments from parents (Rotman & others, 2020)
- Coverage of a recent study that revealed 3- to 4-year-old African American children and children who lived at or below the poverty level were more likely to engage in more than 1 hour of screen time daily, compared with other young children (Kracht, Webster, & Staiano, 2020)
- Inclusion of recent research indicating that infants in a WIC program had higher cognitive scores on the Bayley Scales of Infant Development (Lakshmanan & others, 2020)
- New discussion of the special concern in 2020 about the well-being of young children in low-income families who attend early child care and education programs as many states closed these programs (which provide free meals and snacks) to reduce the spread of the coronavirus (Bauer & others, 2021)
- New data on the millions of children under 5 years of age (38 million) and children and adolescents 5 to 19 years of age (more than 340 million) who are overweight or obese worldwide (World Health Organization, 2020)
- Discussion of a recent study in which a higher level of parental monitoring was linked to adolescents having a healthier diet and reduced likelihood of being overweight (Kim & others, 2019)
- Inclusion of recent research with 10- to 17-year-olds in which obesity was linked to poor academic and coping skills (Gill & others, 2021)
- Updated data from 2017–2018 on the percentage of U.S. adults who are obese, which continues to increase and is now at 42.4 percent (Hales & others, 2020)
- Updated data on obesity rates for gender and ethnicity in the United States (Hales, 2020)
- Inclusion of recent research in which women, especially those who were overweight, reported increased anxiety, depression, and loneliness during the COVID-19 pandemic (Lofrano-Prado & others, 2021)

- New main section on overweight and obesity in older adults, including recent data showing that obesity has a slightly lower incidence in older adults than in middle-aged adults (Centers for Disease Control and Prevention, 2020)
- Coverage of recent research indicating that overweight and obesity in older adults is linked to earlier death (Zhang & others, 2019)
- Inclusion of new content on links between obesity and acceleration of aging (Noale, Limongi, & Magi, 2020)
- Discussion of recent research in which calorie restriction reduced inflammation in normal brain aging and in some neurodegenerative disorders such as Alzheimer disease (Fontana & others, 2020)
- Description of the World Health Organization's (2019) recent guidelines for 3- to 4-year-olds' physical activity, which they emphasized should be 3 hours per day in a variety of physical activities of any intensity, of which at least 60 minutes should be moderate- to vigorous-intensity physical activity, spread throughout the day
- Discussion of recent research indicating that regular physical activity combined with a high calcium intake improved the bone health of 3- to 18-year-olds (Yang & others, 2020)
- Inclusion of a recent research review of 27 studies involving children in which aerobic exercise was associated with reductions in body fat, fasting insulin, and inflammatory markers, as well as increased physical fitness (Lee, 2021)
- Description of a recent research review that concluded physical activity interventions improve cognitive performance (especially executive function) in overweight or obese children (Sun & others, 2021)
- Updated data on the continuing dramatic gender difference in exercise during adolescence, with 30.9 percent of adolescent males engaging in 60 minutes or more of physical activity in each of the last 7 days, compared with only 15.4 percent of their female counterparts (Underwood & others, 2020)
- Updated data on ethnic variations in exercise during adolescence (Underwood & others, 2020)
- Coverage of a recent experimental study that found a 12-week jump rope exercise program was effective in improving obese adolescent girls' body composition, blood pressure, insulin level, and self-regulation (Kim & others, 2020)
- Inclusion of recent research on adolescents with major depressive disorder (MDD) indicating that engaging in aerobic exercise for 12 weeks lowered their depressive symptoms (Jaworska & others, 2019)
- New description of a Chinese study in which adolescents showed more depressive symptoms after the appearance of COVID-19, but engaging in more physical activity during the quarantine helped to buffer the association between the pandemic and depressive symptoms (Ren & others, 2021)
- Discussion of a recent study that confirmed older adults who engage in regular exercise have higher levels of life satisfaction (Cho & Kim, 2020)
- Inclusion of a recent meta-analysis that concluded elastic band resistance training improved older adults' lower-body function and muscle mass (Herda & Nabavizadeh, 2021)
- Description of a recent meta-analysis that confirmed that physically active older adults have a greater likelihood of living longer (Cunningham & others, 2020)
- Coverage of a recent research review that concluded exercise is the most effective behavioral intervention for improving mitochondrial health (Memme & others, 2021)
- Inclusion of a study of middle-aged adults indicating that their estimated age based on exercise stress testing was a better predictor of how long they would live than their chronological age (Harb & others, 2020)
- Discussion of a recent meta-analysis that concluded moderate to vigorous physical exercise reduces depressive symptoms in older adults with an average age of 82 years (Klil-Drori & others, 2020)
- Description of a recent research review of community-dwelling older adults that indicated greater physical exercise was associated with larger brain volume (less brain atrophy) in the hippocampal, temporal lobe, and frontal lobe regions (Domingos, Pego, & Santos, 2021)
- Coverage of a recent meta-analysis that concluded physical exercise training, especially aerobic exercise, improved working memory, executive function, and cognitive flexibility in cognitively healthy older adults (Xiong & others, 2021)
- New content on the lack of exercise by many older adults, with about one in three men and one in two women engaging in no physical exercise by age 75 (Centers for Disease Control and Prevention, 2020)
- Coverage of a longitudinal study that found binge drinking in the twelfth grade was linked to driving while impaired (DWI), riding with an impaired driver (RWI), blackouts, and riskier driving up to 4 years later (Vaca & others, 2020)
- Updated national data on the extent of illicit drug use by U.S. eighth, tenth, and twelfth graders, which is now leveling off (Johnston & others, 2021; Miech & others, 2020). However, if marijuana use is subtracted from overall illicit drug use, there has been a significant decline in adolescent drug use.
- Updated national data on the dramatic increase in the rates of U.S. adolescents who are vaping nicotine, which greatly surpass their rates of regular cigarette smoking (Johnston & others, 2021)
- Description of recent research indicating that not only is e-cigarette smoking a gateway to subsequent combustible cigarette smoking, but it is also a gateway to marijuana use (Fadus, Smith, & Squegia, 2019)
- New coverage of marijuana use in adolescence, which has been increasing considerably in recent years (Johnston & others, 2021)
- Inclusion of recent research that found deviant peer affiliation was linked to multiple substance use (Greenwood & others, 2021)
- New description of a recent study of 15- to 25-year-olds that indicated online peer group affiliation and belonging were linked to stimulant and opioid use (Miller & others, 2021)
- Updated data on binge drinking in college students (Schulenberg & others, 2019)

- Updated data on when binge drinking peaks in the 18- to 30-year age range (Schulenberg & others, 2019)
- New content on the increasing use of marijuana by college students (Schulenberg & others, 2019)
- Inclusion of a recent meta-analysis that found resveratrol (found in red wine) is associated with lower systolic blood pressure (Weaver & others, 2021)
- New discussion of resveratrol's effect on reducing pulmonary arterial hypertension (Mirhadi & others, 2021)
- Coverage of recent research in which resveratrol suppressed tumor growth (Brockmueller & others, 2021)

Chapter 5: Motor, Sensory, and Perceptual Development

- Inclusion of recent research that found gross and fine motor skills early in infancy were linked to communication skills at 2 years of age (Valla & others, 2020)
- Recent research on urban predominately Latinx 6- to 11-year-olds that found low sports participation was linked to higher withdrawn and depressive symptoms (Matta & others, 2021)
- Updated and expanded content on the use of eye-tracking in research involving infants' attention (D'Souza & others, 2020), memory (Edgin & others, 2020), face processing (Wagner & others, 2020), intermodal perception (Ogren & Johnson, 2020), language (Franklin, Wright, & Holmes, 2020), object categorization (LaTourrette & Waxman, 2020), and understanding of others' needs (Koster & others, 2019)
- Coverage of a recent study that found infants' looking times were highest for blue hues and lowest for yellow-green hues (Skelton & Franklin, 2020)
- Updated and expanded discussion of infant pain
- New discussion of research on goal-directed problem solving that involves a coordination of perception and action, including a recent study of preschool children and adults solving a problem of inserting differently shaped objects into corresponding holes in a box (Ossmy & others, 2020). The research found differences in the way the preschool children and adults solved the problem, which involved planning a real-time cascade of perception and action.
- Inclusion of recent research with 8- to 10-year-olds indicating that better gross motor skills were linked to a higher level of visual working memory (van der Fels & others, 2020)
- Coverage of a recent study revealing that experiencing a second hip fracture decreased the longevity of older adults (Trevisan & others, 2020)
- Discussion of recent research that indicated proprioceptive training reduced falls and improved balance and mobility in older adults (Espejo-Antunez & others, 2020)
- Description of a recent study in which exergames improved the mobility and balance of older adults (Pacheco & others, 2020)
- Coverage of a recent study that found declines in visual acuity, contrast sensitivity, and depth perception were associated with cognitive decline in older adults (Swenor & others, 2019)
- Inclusion of a recent study in which hearing impairment was associated with accelerated cognitive decline in older adults (Alattar & others, 2019)
- Discussion of a recent study of older adults in which implementation of hearing aid use was linked to stable or improved executive function (Sarant & others, 2020)
- Description of recent research with individuals 65 years of age and older that found those with olfactory dysfunction died earlier (Choi & others, 2021)
- Coverage of a recent study in which older adults with a dual sensory impairment involving vision and hearing had more depressive symptoms than their counterparts who did not have a dual sensory impairment (Han & others, 2019)
- Inclusion of a recent study of older adults in which high levels of pain were associated with memory impairment (van der Leeuw & others, 2018)
- Description of a recent study that revealed an inability to smell some odors, such as peppermint, was linked to cognitive decline in older adults (Liang & others, 2020)

Chapter 6: Cognitive Developmental Approaches

- Inclusion of a longitudinal study that found attention at 5 months of age was related to A-not-B performance at 10 months and also to executive function in early childhood and reading competence at 6 years of age (Blankenship & others, 2019)
- Description of a recent study of adolescent motorcycle gangs in Indonesia in which their sense of invulnerability was strongly linked to how aggressive they were (Saudi, Hartini, & Barber, 2018)
- In the coverage of Vygotsky's theory, new discussion of a recent study that revealed mothers who engaged in sensitive parenting had children who used more private speech (Day & Smith, 2019)
- New commentary about one cognitive domain—wisdom—that might improve in older adults

Chapter 7: Information Processing

- Coverage of research with 8- to 12-year-olds that found faster processing speed predicted higher language abilities, such as expressive vocabulary (Park & others, 2020)
- Discussion of recent research indicating that slower processing speed was linked to children having ADHD or a learning disability (Kramer & others, 2020)
- Coverage of a recent German study of 40- to 85-year-olds that found higher processing speed was related to greater life satisfaction (Siedlecki & others, 2020)
- Inclusion of recent research that found drivers 70 years of age and older with slower visual processing speed were more likely to have crashes (Swain & others, 2021)
- Description of recent research with fifth-graders in which faster processing speed was linked to better reading fluency and comprehension (Gerst & others, 2021)

- New content indicating that joint attention especially improves between 9 and 12 months of age (Boyer, Harding, & Bertenthal, 2020)
- Description of a recent study in which joint attention was a key factor linking positive parenting with executive function in infants in low-income families (Brandes-Aitken & others, 2020)
- Inclusion of a recent study in which impaired initiation of joint attention at 12 months was linked to subsequent diagnosis of autism spectrum disorder and language delay at age 3 (Franchini & others, 2019)
- Description of recent research with 8- to 18-month-old infants that revealed those from higher-SES families responded to more sophisticated cues for joint attention than infants from lower-SES families (Reilly & others, 2021)
- Coverage of a recent study of 4- to 5-year-olds in which two weeks of training on action-like mini games improved the young children's visuo-spatial attention skills (Nava, Focker, & Gori, 2020)
- Discussion of a recent study that found executive attention was a good predictor of self-regulation (Tiego & others, 2020)
- Description of recent research with 4- to 6-year-olds in which better attention was linked to improved math skills (Cueli & others, 2020)
- Coverage of a recent study in which heavier media multitasking was linked to greater attention lapses and increased forgetting (Madore & others, 2020)
- Expanded coverage of controlling attention in adolescence (Brooker & others, 2020)
- Inclusion of a recent study in which executive attention training improved the selective attention and divided attention of older adults (Yang & others, 2019)
- Discussion of a recent research review that linked game-based training to improved selective attention in older adults (Wang & others, 2021)
- Description of a longitudinal study that followed individuals from 1.5 to 16 years of age and found that the age of first memory increased from 40 to 52 months as adolescents aged from 12 to 16 years of age (Reese & Robertson, 2019). In this study, individual differences in age of first memory were linked to the extent to which mothers had engaged in elaborative reminiscing.
- Inclusion of recent research with preschool children in which better working memory was linked to improved number knowledge (Traverso & others, 2021)
- Description of recent research with first- to third-graders in which working memory improvement predicted gains in math problem-solving skills in bilingual children (Swanson, Arizemendi, & Li, 2021)
- Coverage of research indicating that children with ADHD have working memory deficits (Kofler & others, 2020; Valladares & others, 2020)
- Discussion of recent research confirming that working memory is a foundational cognitive ability, with the frontoparietal network playing a key role in its development (Rosenberg & others, 2020)
- Inclusion of a recent study that revealed Latinx older adults who were more acculturated in the United States had better working memory than their less-acculturated counterparts (Mendoza & others, 2021)
- Coverage of a recent study in which a cognitive training program that increased frontal and parietal lobe brain activity improved older adults' working memory (Gajewski & Falkenstein, 2018)
- Description of a recent study that found longer encoding time improved older adults' working memory (Bartsch, Loaiza, & Oberauer, 2019)
- New discussion of a recent study in which age-related decline in episodic memory impaired access to specific autobiographical events and the details involved (Peters, Fan, & Sheldon, 2019)
- New content on the "reminiscence bump" in autobiographical memories in which older adults often remember more than would be expected from their second and third decades of life (Kowalski & McCord, 2020)
- Coverage of a recent study of 60- to 88-year-olds that revealed the first-time experience of a memory, how important the memory was, and the memory's emotional salience were associated with the reminiscence bump (Wolf & Zimprich, 2020)
- Description of recent research with older adults in which those with mild cognitive impairment showed slower reaction time but had largely preserved implicit memory (Hong & others, 2020)
- Inclusion of recent research indicating that older adults with good retrieval strategies did not show any deficits in source memory (Salhi & Bergstrom, 2020)
- Description of a recent study in which individuals with mild cognitive impairment had impaired prospective memory (Lejeunesse & others, 2020)
- Coverage of a recent study that found a higher level of executive function was related to skill in learning new words (Kapa & Erikson, 2020)
- Discussion of a recent study of preschool children in which lower levels of executive function were associated with inattention and hyperactivity (Landis & others, 2021)
- Description of a recent study in which a lower level of executive function in preschool children was linked to the onset and worsening of attention deficit hyperactivity disorder and depression at 6 to 12 years of age (Hawkey & others, 2019)
- Coverage of a recent study of preschool children in which conditions of socioeconomic disadvantage exerted a stressful influence on parent-child interactions and impaired young children's emergent executive function skills (Baker & Brooks-Gunn, 2020)
- Discussion of a recent study that found children's executive function was a key factor linking early-life family income to later academic achievement (Deer, Hastings, & Hostinar, 2020)
- Inclusion of a recent study of different components of executive function in which inhibition and working memory were associated with children's mindfulness (Geronimi, Arellano, & Woodruff-Borden, 2020)

- Coverage of a recent series of meta-analyses that sought to identify interventions that were most likely to improve children's executive function and found (a) for typically developing children, mindfulness training was effective, and (b) for non-typically-developing children (including those with neurodevelopmental or behavioral problems), strategy teaching focused on self-regulation and biofeedback-enhanced relaxation were the most effective interventions (Takacs & Kassai, 2019)
- Inclusion of a recent study of individuals 10 to 86 years of age in which executive function increased in adolescence and into early adulthood, followed by reductions in working memory and inhibition during the thirties and forties and continued declines in late adulthood (Ferguson, Brunsdon, & Bradford, 2021)
- Discussion of a recent study of older adults in which the highest of four executive function groups was differentiated from the lowest of the four groups by the following factors: education, more novel cognitive activity, lower pulse pressure, younger age, faster gait, lower BMI, and better balance (Caballero & others, 2021)
- Description of a recent study of cognitively healthy older adults that indicated regular physical exercise training, especially aerobic exercise, improved the following key components of executive function—working memory, cognitive flexibility, and cognitive inhibition (Xiong & others, 2021)
- Coverage of a recent study that revealed executive function in older adults increased their sense of control over obstacles that interfered with their ability to attain goals, which in turn was associated with greater life satisfaction (Toh, Yang, & Hartanto, 2020)
- Discussion of recent research in which executive function was linked to positive mood in older adults (Cotter & others, 2020)
- Inclusion of a recent study in which mindful parenting was effective in improving children's social decision making (Wong & others, 2019)
- Description of a recent study in which highly educated older adults had better executive function than their less-educated counterparts, which was associated with slower age-related reduction in executive function (Chen & others, 2019)
- Discussion of a recent research review of 20 executive function training studies which concluded that such training promotes cognitive and neural plasticity in older adults (Nguyen, Murphy, & Andrews, 2019)
- Inclusion of a recent study involving 53- to 86-year-olds in which present-moment attention was linked to better affective well-being (Mahio & Windsor, 2021)
- Coverage of recent research in which a mindfulness-awareness program improved the working memory and divided attention of older adults with mild cognitive impairment (Yu & others, 2021)
- Description of recent research with middle-aged and older adults in which higher mindfulness was associated with more positive aging expectations (Fiocco & Meisner, 2020)
- Discussion of a recent study of older Mexican adults that revealed in addition to one's own education, a spouse's education also was associated with better cognitive ability (Saenz & others, 2020)
- Coverage of recent research indicating that a higher level of education has a strong effect on older adults' working memory (Saito & others, 2020)
- Inclusion of a recent study of Puerto Rican older adults that revealed a higher level of cognitive complexity in work was associated with a lower risk of cognitive impairment (Andel & others, 2019)
- Description of a recent study of older Latinxs that found cardiovascular risk factors were linked to lower cognitive function (Tarraf & others, 2020)
- Coverage of a recent study that revealed high blood pressure was associated with lower cognitive function in older adults (Naharci & Katipoglu, 2021)
- Discussion of a recent study of older adults that found depression was linked to lower executive attention, memory, and language performance (MacAulay & others, 2020)
- Inclusion of recent research that indicated the risk of cognitive decline was lower in older adults who engaged in either moderate-to-high intensity exercise or low-intensity exercise (Endeshaw & Goldstein, 2021)
- Coverage of research involving two different samples of older adults in which a higher level of cognitive activity was related to better cognitive functioning (Casaletto & others, 2020)
- Coverage of a study of more than 1,000 middle-aged and older adults in which overall cognitive decline accelerated considerably at 3.7 years on average before death (Wilson & others, 2020). In the same study, terminal decline accounted for a significant percentage of decline in specific cognitive processes—for example, 70 percent of the decline in episodic memory.
- Discussion of the Mayo Clinic Study of Aging (Krell-Roesch & others, 2019) in which engaging in a higher number of mentally stimulating activities (book reading, computer use, social activities, game playing, and craft activities) was associated with a decreased risk of mild cognitive impairment
- Coverage of a recent study of older adults in China that linked high levels of both cognitive activity and physical activity with greater capacity to maintain and preserve cognitive function (Wu & others, 2021)
- Inclusion of a recent research review that concluded low levels of social isolation characterized by high engagement in social activity and large social networks were linked to better cognition (memory and executive function, for example) in older adults (Evans & others, 2019)
- New commentary noting that cognitive gains from cognitive training games are typically constrained to the specific task being assessed and do not generalize to broader cognitive function (Rogers, Blocker, & Dupuy, 2020)
- Coverage of a recent study of older adults that found an in-home exergame training program improved their executive function (Adcock & others, 2020)
- Description of a recent study of 7- and 8-year-olds in which task-specific metacognitive monitoring skills in noticing one's own errors and learning from mistakes were linked to superior performance in arithmetic (Bellon, Fias, & DeSmelt, 2019)

Chapter 8: Intelligence

- New description of Sternberg's (2021a, b) view of successful intelligence that emphasizes the importance of setting and accomplishing personally meaningful goals. His view also stresses that goal setting involves exploring and figuring out one's own strengths and weaknesses and capitalizing on the strengths while also correcting or improving on the weaknesses.
- New coverage of a recent meta-analysis in which emotional intelligence was the third best predictor of academic performance, following general intelligence and the personality trait of conscientiousness (MacCann & others, 2020)
- Discussion of a recent survey of 102 experts on intelligence around the world that found most experts supported the concept of general intelligence (*G*) (Rindermann, Becker, & Coyle, 2020)
- Inclusion of a recent Danish study in which IQ test scores were positively associated with educational attainment in early and middle adulthood (Hegelund & others, 2020). Also in this study, individuals with low intelligence in childhood benefitted the most from education.
- New coverage of content on how IQ gains continue to occur in the United States and developing countries (Flynn, 2020)
- New discussion of Sternberg's (1998, 2019) balance theory of wisdom
- New description of the views of Igor Grossman and his colleagues (2020) and Judith Gluck (2020) stating that wisdom involves balancing your perspectives with those of others and being motivated to attain some common good within a larger group, such as one's family, an institution, or even a country. These experts believe that metacognitive thinking with a moral grounding is a critical factor in attaining wisdom.
- Updated estimate of the percentage of children who are classified as gifted in the United States (National Association for Gifted Children, 2020)
- Inclusion of Sternberg's (2018) recent view of giftedness, which he believes should include not only assessment of successful intelligence but also wisdom
- New quotation that supports the role of intellectual risk-taking in creativity

Chapter 9: Language Development

- Inclusion of changes and updates based on feedback from leading expert Virginia Marchman
- Discussion of a recent study in which infants at high risk for autism spectrum disorder used fewer gestures than their counterparts who were at low risk for autism (Choi & others, 2021). Also in this study, parents who gestured more with their 12-month-old infants had children with a better vocabulary at 36 months.
- Expanded content on Richard Aslin's (2020) conclusions that in addition to word segmentation, statistical learning has been documented as important in other domains such as musical tones, phonetic categories, sequences of visual shapes, sequences of motor responses, and combination of object parts in complex visual scenes
- New content on the variability of the ages when infants and toddlers learn new words as well as the timing of vocabulary spurts. Also, new commentary on how some children experience a vocabulary spurt while others make slow and steady progress in learning new words.
- Description of a recent study in which learning new words at 21 months was associated with receptive vocabulary at 7 to 10 years of age (Rajan & others, 2019)
- Coverage of a recent study in which conversational turn counts at 18 to 24 months were linked to receptive and expressive vocabulary development 10 years later (Gilkerson & others, 2018)
- New discussion of a study involving English-speaking preschool children that revealed those from lower-income families had less advanced language-processing skills, as well as a smaller vocabulary and syntax deficiencies (Levine & others, 2020)
- Inclusion of recent research with low-income families in which 15-month-old infants whose mothers had a college education had much better language skills than their low-income counterparts whose mothers did not have a college education, and these differences were still present at 3 years of age (Justice & others, 2020)
- Coverage of a recent meta-analysis in which sensitive responsiveness by parents in low-SES families was more strongly linked to improvement in young children's language development than was the case in middle- and high-SES families (Madigan & others, 2019)
- Description of a recent study that found children living in extreme poverty had much smaller vocabularies and lower reading comprehension (Lervag & others, 2019)
- New *Connecting with Research* interlude on the effects of communication difficulties between hearing parents and deaf children
- Discussion of recent research in which teacher-perceived conflict predicted lower interest and pre-academic literacy skills in young children (Pakarinen & others, 2021)
- New coverage of the important concept of "learning to read" versus "reading to learn," with information regarding the typical timing of the switch between these two modes of reading
- Inclusion of a recent analysis across a number of countries that found bilingual children consistently had better executive function than monolingual children (Schirmbeck, Rao, & Maehler, 2020)
- Description of a recent study indicating a bilingual advantage for the alerting subcomponent of attention (Dash & others, 2019)
- New commentary that some recent research studies have not found a cognitive advantage for bilingual children (Dick & others, 2019; Donnelly & others, 2019)
- Discussion of recent research by Virginia Marchman and her colleagues (2020) in which early Spanish language development at 2 years of age was linked to stronger English

skills and maintenance of good Spanish language skills at 4½ years of age

- Coverage of recent research with young children that found shared book reading at home and school in a second language not only improved their second-language learning but also that the perspective taking emphasized in the shared reading program increased the children's ability to shift perspectives and understand others' emotional states (Grover & others, 2020)
- New discussion of a recent study of Chinese children indicating that English as a foreign language bilingual children outperformed monolingual Chinese children on an attention task and also had higher activation of their prefrontal cortex (Li & others, 2019)
- Inclusion of a recent study that confirmed older adults have more difficulties in narrative discourse than younger age groups (Babaei & others, 2019)
- Coverage of a recent study of individuals with mild cognitive impairment in which those who were bilingual had better verbal memory than their monolingual counterparts (Rosselli & others, 2019)
- Description of research with 59- to 79-year-olds in which a 4-month-long second language program produced improvements in global cognitive functioning and connectivity among different regions of the brain's frontal and parietal lobes (Bubbico & others, 2019)
- Discussion of a recent study that found parental coaching at 6, 10, and 14 months of age involving child-directed speech, back-and-forth interactions, and parentese speech increased infants' conversational turn-taking and language skills (production of words, for example) at 18 months of age (Ferjan Ramirez & others, 2020)
- Inclusion of a recent study of 9- to 18-month-old infants in which book sharing resulted in more parent talk, child talk, and interactions than other language activities (toy play, personal care, and mealtime interactions, for example) (Clemens & Kegel, 2021)
- Description of a recent meta-analysis that concluded shared picture book reading was linked to children having better expressive and receptive language skills (Dowdall & others, 2020)
- Coverage of a recent study that revealed parent-child book reading interactions with 1- to 2.5-year-olds were linked to better language development in terms of receptive vocabulary, reading comprehension, and motivation to read in elementary school (Demir-Lira & others, 2019)

Chapter 10: Emotional Development and Attachment

- Revisions based on feedback from leading experts Martha Ann Bell and Laura Carstensen
- Discussion of recent research on healthy, full-term newborn crying duration using a digital recording device that indicated the average crying time is greater than previously indicated in parent reports of infant crying duration (Cabana & others, 2021)
- Inclusion of a recent research review that concluded young children's emotion regulation at 3 to 5 years of age plays an important role in preparing children for school readiness for kindergarten and elementary school in both socioemotional and academic domains (Harrington & others, 2020)
- Coverage of a recent study that found emotion-dismissing mothers' parenting was linked to toddlers' lower emotional competence while mothers' emotion-coaching parenting was associated with their toddlers' higher emotional competence (Ornaghi & others, 2019)
- Description of a recent study involving 3- to 4-year-olds in which paternal emotion coaching predicted children's positive emotional expression one year later (Gerhardt & others, 2020)
- Coverage of a recent Chinese study in which the "Tuning in to Kids" program that emphasizes emotion coaching was effective in improving the emotion coaching and decreasing the emotion dismissing of mothers of preschool children (Qiu & Shum, 2021)
- New summary of key supportive and unsupportive caregiver emotion socialization with children based on research in the last two decades (Spinrad, Morris, & Luthar, 2020)
- Inclusion of a recent study that found letting infants cry it out in the first six months was not linked to adverse behavioral development and attachment at 18 months of age (Bilgin & Wolke, 2020)
- Description of a recent study that revealed when parents let their infant cry it out, it was associated with highly problematic behavior at 3 months of age but with reduced problematic behavior at 12 months of age (Giesbrecht & others, 2020)
- Discussion of a longitudinal study that revealed happiness at 1.5 years of age predicted intelligence in childhood (6 to 8 years of age) and educational attainment in adulthood (29 years of age) (Coffey, 2020)
- Coverage of a recent study that indicated when fear was assessed at 6, 8, 10, and 12 months, fear peaked at 10 months (Gartstein, Hancock, & Iverson, 2018)
- Inclusion of a recent study of young children in which a lower level of maternal depression and a higher level of children's executive control predicted a higher level of children's emotion knowledge (Thompson & others, 2020)
- Description of a recent study in which children's emotion regulation, expressed in being able to manage feelings of sadness and worry, served as a buffer against the internalized symptoms associated with peer victimization (Cooley & others, 2021)
- Coverage of a recent study in which young children with better emotion regulation were more popular with their peers (Nakamichi, 2020)
- Discussion of a recent study of preschool children in which frequent expression of anger predicted lower social competence one year later (Lindsey, 2019)
- Inclusion of recent research in which girls had higher emotion regulation skills at 9 to 12 years of age than at 13 to 16 years of age, while the reverse occurred for boys (Sanchis-Sanchis & others, 2020)

- New section, "Social-Emotional Education Programs" (DiPerma, Frey, & Hart, 2021), including two increasingly implemented school programs: Second Step and CASEL
- New coverage of a recent study that found better self-regulation at 10 years of age was linked to maternal support at 5 years of age and also predicted better adolescent adjustment at 15 years of age (Perry & others, 2020)
- New commentary on the stress that the coronavirus pandemic has caused for children and some strategies parents can use to help children cope with the uncertainties of the virus
- Inclusion of a recent meta-analysis that found anxiety, depression, irritability, boredom, inattention, and fear were the main new-onset psychological problems that occurred in children during the COVID-19 pandemic (Kumar Panda & others, 2021)
- Extensive revision of the discussion of adolescent depression in the section on adolescent emotional development
- Coverage of a recent study in which low self-esteem and negative emotion management were linked to adolescent depression (Fiorilli & others, 2019)
- Description of recent research in which interpersonal stress was linked to increased depression in adolescent girls (Slavich & others, 2020)
- Coverage of a recent study in which higher levels of maternal and peer emotion support were linked to lower levels of adolescent girls' daily negative affect and also predicted increases in the girls' emotion regulation over time (Cui & others, 2020)
- Inclusion of a recent research review that concluded adolescents are very poor at recognizing depression, more likely to seek help from informal rather than professional sources, and tend to attach stigma to depression (Singh, Zaki, & Farid, 2019)
- Discussion of a longitudinal study that found a majority of adolescents who had a major depressive episode were likely to experience a recurrence of depression 15 years later (Alaie & others, 2019). In addition, depression during adolescence was associated with other mental health problems, low educational attainment, and problems in intimate relationships 15 years later.
- Description of a number of changes in the coverage of emotional development and aging based on feedback and editing by leading expert Laura Carstensen, including a revised description of her social selectivity theory
- Coverage of a recent study of 18- to 76-year-olds revealing that even during the prolonged stress of the COVID-19 pandemic, older adults reported more positive and less negative emotion than younger participants (Carstensen, Shavit, & Barnes, 2020)
- Expanded recommendations on parenting strategies for improving infants' and children's temperament
- Discussion of a recent study of low-income families in which having a difficult temperament at 0 to 12 months of age predicted behavior problems at 36 months (Maltby & others, 2019)
- Coverage of a recent study in which Latinx infants were at increased risk for obesity when their mothers had an anxious or avoidant insecure attachment style than a secure attachment style (Hepworth & others, 2021)
- Inclusion of a recent longitudinal study in which insecurely attached infants had worse emotion-regulation strategies than their securely attached counterparts in relationship-challenging contexts 20 to 35 years later (Girme & others, 2021)
- Description of a recent research review concluding that DNA methylation associated with infant attachment may influence stress regulation and socioemotional function (Craig & others, 2021)
- Updated data on the percentage of fathers who are staying at home and caring for their children (Livingston, 2018)
- New commentary about the increasing number of fathers who are working at home and likely to be around their children more than in the past because of the COVID-19 pandemic
- Coverage of a recent NICHD study that found sensitive, nurturing care of 6- to 54-month-olds predicted a higher incidence of prosocial behavior in first-grade children (Brownell & Drummond, 2020)
- New discussion of research indicating that adolescents who are insecurely attached are more likely to have emotional difficulties and engage in problem behavior such as drug abuse (Theoret & others, 2020)
- Description of a recent study of Lebanese adolescents that found those who were securely attached had lower rates of addiction to alcohol and cigarettes than their insecurely attached counterparts (Nakhoul & others, 2020)
- Coverage of a recent Israeli study in which avoidant and anxiously attached adolescents were less effective in coping with stress (Agbaria, 2021)
- Inclusion of a recent study that indicated maltreated and delinquent adolescents had high levels of insecure attachment (Protic & others, 2020)
- Discussion of a research review that revealed insecure attachment styles increased the risk of engaging in suicidal thoughts (Zortea, Gray, & O'Connor, 2021)
- Description of a recent study that indicated college students with an anxious attachment style were more likely to be addicted to social networking sites (Liu & Ma, 2019)
- Coverage of a recent meta-analysis that revealed adults with insecure attachment styles were more likely to engage in risky sexual behaviors (Kim & Miller, 2020)
- Updating and rewriting of section on attachment in late adulthood for greater clarification
- Discussion of a recent study in which older adult females with an avoidant attachment style were more likely to be socially isolated (Spence, Jacobs, & Bifulco, 2020)
- Description of a recent study of older adults that revealed those with secure attachment were competent in daily life, which in turn was related to psychological adjustment (Martin, Horn, & Allemand, 2021)
- Inclusion of a recent study that revealed a higher level of anxiety and depression symptoms in mothers in the last trimester of pregnancy was associated with infants' externalizing problems at 2 years of age and a higher level of these

symptoms in fathers in the last trimester of pregnancy was related to a higher level of infants' internalized and externalized problems at 14 months of age (Hughes & others 2020)

- Description of a recent study involving the Bringing Home Baby project that found fathers who participated in the program felt more appreciated by their wives and that the mothers of the infants were more satisfied with the division of labor when fathers were more involved in parenting (Shapiro, Gottman, & Fink, 2020)
- Coverage of a recent study in which greater self-disclosure was associated with higher relationship intimacy offline but with lower relationship intimacy with romantic partners but not friends online (Lee, Gillath, & Miller, 2019)
- Discussion of a recent study that found being in a romantic relationship, interacting with a partner, and investing more time and effort in the relationship all predicted greater well-being (Hudson, Lucas, & Donnellan, 2020). However, these effects were moderated by relationship quality.
- Inclusion of information from a recent national poll of singles in the United States regarding how the COVID-19 pandemic had changed their dating habits (Match.com, 2020)
- Coverage of a recent cross-cultural study of more than 7,000 individuals in 25 countries that found support for the universality of Sternberg's triarchic theory of love (Sorokowski & others, 2021)
- New *Connecting with Research* interlude exploring the challenges of dealing with unrequited love (Clark & others, 2020)

Chapter 11: The Self, Identity, and Personality

- Discussion of recent research that revealed perspective taking underlies children's prosocial behavior and that the capacity to take others' perspectives develops during the early elementary school years (Sobel & Blankenship, 2021)
- Inclusion of recent research indicating that children who engage in less perspective taking are less likely to give to others (van de Groep, Zanolie, & Crone, 2020)
- Coverage of a recent research review in which reminiscence therapy with older adults was linked to reduced depressive and anxiety symptoms, improved life satisfaction, and increased social engagement (Shropshire, 2020)
- Inclusion of a recent study that revealed reminiscence therapy reduced the cognitive impairment, anxiety, and depression of post-stroke patients (Cheng & others, 2021)
- Description of recent research indicating that reminiscence therapy improved the cognition and quality of life of Alzheimer disease patients (Perez-Saez & others, 2021)
- New section on narcissism (Weiss & others, 2021)
- New content on the important distinction between vulnerable narcissism and grandiose narcissism and their links to different outcomes (Donnellan, Ackerman, & Wright, 2021)
- Coverage of a recent study that found grandiose narcissists actually were characterized by greater life satisfaction than vulnerable narcissists but also were characterized as inauthentic (Kaufman & others, 2020)
- Discussion of a recent study of Chinese adolescents in which mental health outcomes of narcissists depended on their self-esteem—narcissism and high self-esteem were associated with positive mental health outcomes, while narcissism and low self-esteem were linked to problematic mental health outcomes (Xu, Huebner, & Tian, 2020)
- Description of a recent study in three countries—Brazil, Portugal, and Spain—that found parental warmth was a key factor in adolescent self-esteem in all three countries (Isabel Martinez & others, 2020)
- Inclusion of a recent study in which parental warmth, monitoring, low maternal depression, economic well-being, and father presence (versus father absence) were linked to higher self-esteem in children and adolescents (Krauss, Orth, & Robins, 2020)
- Discussion of a 10-year longitudinal study in which high self-esteem in adolescence predicted more long-term personal goals, better self-rated physical health, and fewer depressive symptoms in emerging adulthood (Arsandaux, Galera, & Salamon, 2021)
- Updated and expanded coverage of outcomes of self-esteem levels in a number of areas, including sexual health (Sakaluk & others, 2020)
- Inclusion of a longitudinal study with Mexican-origin adolescents in which a reciprocal relation between self-esteem and academic achievement was found (Zheng & others, 2020)
- Description of a meta-analysis that concluded the findings did not support the notion that self-evaluations reach a critical low point in many domains in early adolescence (Orth & others, 2021)
- Coverage of a recent study that revealed maternal and paternal positive parenting (positive mood, good communication skills, and assertiveness) were associated with higher effortful control in young children (Neppl & others, 2020)
- Inclusion of recent research indicating that a majority of 4- to 5-year-old children were developmentally on track with self-regulation (Claussen & others, 2021). However, compared with children described as not on track, those who were on track lived in financially and socially advantaged environments and were less likely to undergo family adversity.
- Expanded and updated coverage of the importance of self-regulation in adolescence (Casey & others, 2019)
- Description of a recent meta-analytic review in which low self-regulation at 8 years of age was linked to externalizing problems, depressive symptoms, obesity, cigarette smoking, and illicit drug use at 13 years of age (Robson, Allen, & Howard, 2020)
- Coverage of a longitudinal study from birth to 45 years of age that revealed individuals with better self-control in childhood aged more slowly physically as adults and had fewer signs of aging in their brains (Richmond-Rakerd & others, 2021). Also in this study, in midlife these individuals were better equipped to manage later-life health, financial, and social demands.
- Discussion of a recent study of 13- to 16-year-olds in which females reported having a higher level of self-control and self-monitoring than their male counterparts (Tetering & others, 2020)

- Inclusion of a recent study of Mexican-origin adolescents identifying the factors in their lives that were linked to different levels of effortful control (Atherton, Lawson, & Robins, 2020)
- Coverage of a recent study in which selective optimization with compensation (SOC) strategies improved the job performance of adults when they were faced with intense job demands (Mauno & others, 2020)
- Inclusion of a recent study in which SOC strategies were linked to successful aging in Korean women (Han & Ko, 2021)
- Description of a recent study that revealed emerging adults who were identity confused were more likely to present an ideal self and a false self on Facebook, indicating they were less realistic and more socially desirable in their online self-presentation (Michikyan, 2020)
- New discussion of a longitudinal study from early adolescence to emerging adulthood that confirmed the existence of a dual-cycle identity formation process (Becht & others, 2021)
- Discussion of a recent study of Flemish 17- to 26-year-olds in northern Belgium in which commitment and responsibility characterized older and employed participants more than younger and unemployed participants (Mattys & others, 2020)
- New coverage of a study of identity development from 25 to 33 years of age (Eriksson & others, 2020). In this study, fewer individuals were characterized by a moratorium status and more by an identity achievement status as they became older during this time frame.
- Much expanded and updated coverage of ethnic and racial identity based on feedback from leading expert Kevin Cokley
- New coverage of racial identity
- Inclusion of recent research on 13- to 17-year-old African American girls' racial socialization revealing that pride was linked to positive feelings about being Black while depression was associated with oppressive messages about Black women (Stokes & others, 2020)
- Description of a recent study of 11- to 12- year-olds that found more frequent discrimination from peers was linked to lower ethnic-racial commitment (Del Toro, Hughes, & Way, 2021)
- Coverage of a recent study of adolescents that revealed on days when adolescents reported more negative peer ethnic/racial interaction, they had lower school engagement (Wang, 2021). Also in this study, on days when they reported more positive peer ethnic/racial interaction, they engaged in more prosocial behavior.
- Inclusion of a recent research review of Latinxs that concluded perceived discrimination was linked to poorer mental health but that having a greater sense of ethnic pride attenuated this link (Andrade, Ford, & Alvarez, 2021)
- New discussion of the singular concept of ethnic-racial identity (ERI) (Atkin & others, 2021)
- Description of a recent study of Cherokee young adolescents' ERI in which both girls and boys reported strong positive attitudes about being a Cherokee (Hoffman, Kurtz-Coates, & Shaheed, 2021). However, youths' perceptions that others hold Cherokees in high regard decreased across the years.
- Coverage of a recent study that revealed enhanced resilience against discrimination in Latinx youth when they had more experiences with ethnic family socialization and had engaged in ethnic identity exploration and resolution (Martinez-Fuentes, Jager, & Umaña-Taylor, 2021)
- Expanded and updated discussion of the Big Five Factors of personality, including links to mental health (Widiger & McCabe, 2021) and achievement (Szalma, 2021)
- Discussion of a recent study of the Big Five factors in which conscientiousness was the strongest predictor of living longer (Chapman & others, 2020). In this study, the activity dimension of extraversion was a better predictor of longevity than other dimensions.
- Description of a recent study that indicated adolescents high in conscientiousness are less likely to spend excessive time on social networking sites (Yanez & others, 2020)
- Coverage of a recent study that revealed adolescents high in conscientiousness have greater satisfaction with life (Heilmann & others, 2020)
- Inclusion of recent research indicating that adults high in conscientiousness are more satisfied with their marriage, while those high in neuroticism are less satisfied with their marriage (Sayehmiri & others, 2020)
- Description of a recent study that found adults high in extraversion had a higher perceived level of well-being (Ortet & others, 2020)
- Coverage of recent research indicating that individuals high in agreeableness were less likely to engage in physical activity (Hearon & Harrison, 2020)
- Discussion of recent research that revealed individuals characterized by high neuroticism avoided engaging in selfie-posting and selfie-editing, while those with high extraversion and agreeableness engaged in more selfie-posting and selfie-editing (Chaudhari & others, 2019)
- Inclusion of a recent study of adolescents in which high neuroticism was linked to having more symptoms of anxiety, depression, and obsessive-compulsive disorder (Tonarely & others, 2020)
- Inclusion of a recent study in which older adults with higher neuroticism and lower conscientiousness had more difficulty in their cognitive control of processes needed to engage in goal-directed behavior (Bell, Hill, & Stavrinos, 2020)
- Coverage of recent research with adolescents indicating that higher levels of optimism were linked to lower levels of suicide risk (Yi & others, 2021)
- Discussion of a recent study of Latinx young adolescents that found higher resilience and school attachment predicted higher optimism (Taylor & others, 2020)
- Description of a recent study that revealed regardless of growing up in disadvantaged circumstances as a child, being optimistic as an adult was linked to being a non-smoker, consuming a healthy diet, and having a healthy body mass index (Non & others, 2020)

- Inclusion of recent research that revealed greater optimism at 85 and 90 years of age was associated with five-year survival from 85 to 90 and from 90 to 95 (Jacobs, Maaravi, & Stessman, 2021)
- New *Connecting with Research* interlude exploring how an individual's personality profile might be connected to their diversity orientation and attitudes about diversity
- Coverage of a recent study of college students in which daily hassles predicted subsequent health complaints (Tran & others, 2021)
- Discussion of recent research in which a 6-week generativity program with middle-aged and older adults produced positive outcomes including increases in perceived social support and decreases in loneliness (Moieni & others, 2021)

Chapter 12: Gender and Sexuality

- Extensive editing, revision, and updating based on leading expert Sabra Katz-Wise's feedback and comments
- Description of a recent study with 18-month-olds in which fathers with higher testosterone levels were more likely to engage in child maltreatment and negative parenting (Rodriguez, Granger, & Leerkes, 2021)
- Inclusion of recent research with 15- to 39-month-olds that revealed mothers tended to protect young children from distress, while fathers were more likely to assist their children in coping with frustration (Deichmann & Ahnert, 2021)
- Discussion of a recent study of 4- to 9-year-olds in which gender-nonconforming children were perceived more negatively than gender-conforming children (Kwan & others, 2020). Also in this study, gender-nonconforming boys were perceived more negatively than gender-nonconforming girls.
- Inclusion of recent research that found young adolescent boys were more likely to feel pressure from parents to engage in gender-conforming behavior and to feel pressure from peers to avoid engaging in gender-nonconforming behavior (Jackson, Bussey, & Myers, 2021)
- New *Connecting with Research* interlude exploring preschool children's perceptions of gender and careers
- Coverage of a recent study of 3- to 7-year-olds that revealed boys were more likely than girls to engage in gender stereotyping, especially with masculine stimuli such as toys, and to be sanctioned for not conforming to gender stereotypes (Skocajic & others, 2020)
- Inclusion of recent research with 14- to 18-year-olds that found believing in innate math ability was associated with lower self-perceived ability and intrinsic motivation in girls but not in boys (Heyder, Weidinger, & Steinmayr, 2021)
- New commentary noting that categories such as gender and ethnicity intersect and create systems of power and privilege as well as oppression and discrimination
- Updating of national scores in eighth-grade math (National Assessment of Educational Progress, 2019a) and fourth-grade reading (National Assessment of Educational Progress, 2019b), with gender scores virtually even in math but girls still scoring higher than boys in reading
- Inclusion of a recent study of preschool children that found differences favoring girls on a wide range of pre-academic and cognitive skills, including attention, language, and literacy (Brandlistuen & others, 2020)
- New coverage of recent research that revealed girls show more emotional concern for others than boys do (Trentini & others, 2021)
- New description of a recent study that found girls had much better self-regulation than boys at 13 to 16 years of age (van Tetering & others, 2020)
- Extensively edited, expanded, and updated coverage of transgender individuals
- New discussion of the term *two-spirit* that is used by some indigenous North Americans to refer to individuals who are perceived as having both male and female spirits within them
- New content indicating that 40 percent or more of transgender individuals attempt suicide at least once (Dickey & Budge, 2020)
- Coverage of a recent study of transgender individuals in which gender affirmation was associated with a lower rate of suicidal ideation and psychological distress, while discrimination was linked to a higher rate of suicidal ideation and psychological distress (Lelutiu-Weinberger, English, & Sandanpitchai, 2020)
- Description of recent research that confirmed victimization and discrimination predicated increased suicidal ideation, while community connection reduced suicidal ideation (Rabasco & Andover, 2021)
- Inclusion of a recent study that found a majority of transgender individuals had experienced discrimination in the last year and those who encountered greater discrimination were more likely to experience depression and anxiety (Puckett & others, 2020)
- New commentary that because trans individuals experience considerable discrimination, it is important that society provide a more welcoming and accepting attitude toward them (Vargas, Huey, & Miranda, 2020)
- Coverage of a recent study that found psychotherapy targeting internalized stigma and non-affirmation experiences can be effective in reducing gender-related stress and increasing resilience in transgender persons (Budge, Sinnard, & Hoyt, 2020)
- New *Connecting with Careers* feature on Dr. Stephanie Budge, psychotherapist and researcher focusing on transgender issues
- Inclusion of recent research indicating increased rates of sexual inactivity among young adults from 2008 to 2018 and possible reasons for this increase (Ueda & others, 2020)
- Discussion of a recent study of young adolescents at 14 sites across 4 continents that found consistent evidence for a sexual script of boys' social gains for having girlfriends and girls' risk for having boyfriends (Moreau & others, 2018)
- Inclusion of recent research indicating that sexual minorities' reports of general discrimination, victimization, and health care discrimination peaked in early adulthood and again in middle adulthood (Rice & others, 2021)

- Updated data on the number of people in the U.S. living with an HIV infection (1.2 million), with 1 in 7 of these individuals unaware that they have the infection (HIV.gov, 2020)
- Updated statistics noting that approximately 36,400 new HIV infections were diagnosed in 2018, with 69 percent of those diagnoses given to men who were having sex with other men (HIV.gov)
- New content on the increasing interest in PrEP (pre-exposure prophylaxis) awareness, which involves taking a daily pill that can reduce the probability of getting HIV by as much as 90 percent (Restar & others, 2020)
- Inclusion of a recent study in which more than 87 percent of alcohol-involved sexual assaults on college campuses was committed by serial perpetrators (Foubert & others, 2020). Also in this study, fraternity members and student athletes were more likely to commit alcohol-involved assault than other men on campus.
- Coverage of a recent study that indicated women who had experienced sexual assault were more likely to subsequently have more academic problems and engage in fewer serious romantic relationships while in college and nine years later to have more symptoms of depression, anxiety, and post-traumatic stress disorder (Rothman & others, 2020)
- Inclusion of recent research on acquaitance rape of college women that revealed 84 percent of the women knew their perpetrator and 65.5 of them encountered the perpetrator after the attack (Bell, Wolff, & Skolnick, 2021). Women who encountered their perpetrator after the attack reported more lifestyle changes and more severe symptoms of post-traumatic stress disorder.
- New content on the recent movement toward *affirmative consent* for sexual activity that is being encouraged on many college campuses (Goodcase, Spencer, & Toews, 2020)
- Discussion of a recent study of young adults in which women (37.4 percent) were more likely than men (22.4 percent) to report having experienced sexual assault (Mumford & others, 2020)
- Inclusion of a recent national study that focused on sexting among U.S. middle and high school students (Patchin & Hinduja, 2019)
- Updated national data (2019) from the Youth Risk Behavior Surveillance study on the timing of sexual intercourse in U.S. adolescents, including ethnic variations and the percentage of adolescents who start having sexual intercourse prior to 13 years of age (Underwood & others, 2020)
- New projections from the National Survey of Family Growth for the probability of having sexual intercourse in the United States by the age of 20, which is 77 percent for males and 79 percent for females (Martinez & Abma, 2020)
- Description of a recent study of adolescents that indicated higher quality of experiences with parents were linked to reduced likelihood of accessing pornography or engaging in vaginal sex, anal sex, oral sex, and masturbation (Astle, Leonhardt, & Willoughby, 2020)
- New coverage of a recent study in which associating with antisocial peers predicted early engagement in sexual intercourse (Clark & others, 2021)
- New discussion of a recent study of adolescents that linked low self-control to risky sexual behavior (Magnusson, Crandall, & Evans, 2020)
- Coverage of a recent national study that indicated adolescent use of long-acting reversible contraception (LARC) increased from 1.8 percent in 2013 to 5.3 percent in 2017 (Aligne & others, 2020)
- Updated data on the incidence of adolescent pregnancy in the United States, which continues its dramatic decline, reaching its lowest point ever in 2019—16.7 births per 1,000 15-to 19-year-olds, less than half the percentage (41.5 births) in 2008 (Martin & others, 2021)
- Updated data on ethnic variations in the incidence of adolescent pregnancy, with significant declines in Latinx, African American, non-Latinx White, and Asian American adolescent pregnancies
- Coverage of recent research on the percentage of adolescents who use condoms when they have sex, including ethnic variations (Szucs & others, 2020)
- Description of a study in which use of LARC increased from 2010 to 2017, although urban, educated, and higher-income women were more likely to use LARC (Beshar & others, 2021)
- Updata on AIDS incidence worldwide, with 88 percent of all children and adolescents with AIDS living in sub-Saharan Africa (UNAIDS, 2020)
- Inclusion of a recent Canadian study that found adolescent mothers were much more likely than young adult mothers to live in low-SES neighborhoods, be depressed, and have higher rates of tobacco, marijuana, and alcohol use (Wong & others, 2020)
- Update on pregnancy prevention programs provided by Girls Inc (2021), including recent research indicating that their adolescent pregnancy prevention program was effective in preventing pregnancy
- Update on the continuing government funding of pregnancy prevention programs through the Office of Adolescent Health (2021) and a description of the focus of several of the programs
- Description of a recent research review and analysis that concluded research over the last three decades strongly supports the value of comprehensive sex education across a range of topics and grade levels (Goldfarb & Lieberman, 2021)
- Coverage of recent research in which across the college years, rates of kissing, touching, performing and receiving oral sex, and penetrative sex increased (Lefkowitz & others, 2019). Also in this study, across the college years, contraceptive use decreased, especially for males and for students in a serious romantic relationship.
- Discussion of a recent study of first-year college students in six focus groups that found the following was a common theme in their discussion: "Sex is easier to get and love is harder to find" (Anders & others, 2020)
- Description of a recent study of emerging adults in which a higher percentage of women than men reported having sex, hooking up with an acquaintance, using partner characteristics as a reason to hook up, and having negative reactions to

their most recent hookup (Olmstead, Norona, & Anders, 2019). Also in this study, a higher percentage of men reported hooking up with a stranger, meeting at a bar/club, and hooking up at a party.

- Coverage of a recent study of more than 300,000 women that found late menopause was associated with increased risk of breast cancer (Gottschalk & others, 2020)
- Inclusion of a recent research review that concluded TRT is effective in improving sexual function but that evidence of its influence on other outcomes, such as cardiovascular disease, is inconclusive (Corona, Torres, & Maggi, 2020)
- New content on a number of factors that are linked to erectile dysfunction, such as smoking, cardiovascular issues, obesity, depression, and lack of exercise (Crafa & others, 2020)
- New description of high-intensity shockwave therapy for the treatment of erectile dysfunction (Adeldaheim & others, 2021)
- Coverage of a recent research review of low-intensity shockwave therapy that showed benefits in treating erectile dysfunction after 6 months and continued but reduced effects at 1 year (Brunckhorst & others, 2019)
- Description of a recent study in which a combined treatment of low-intensity shockwave therapy and Cialis was more effective in reducing ED than Cialis alone (Verze & others, 2020)
- New discussion of a recent study of individuals 50 years and older that revealed a past-year decline in sexual desire or frequency of sexual activities was associated with an increase in depressive symptoms and a lower quality of life (Jackson & others, 2019)
- Coverage of a recent study that found middle-aged and older adult women reported greater sexual satisfaction when they had fewer physical illnesses, better self-rated health, and absence of depression, and when they placed higher importance on sexuality and intimacy (Buczak, Konig, & Hajek, 2021). Also in this study, greater sexual satisfaction was linked to having a partner, living with a partner, and being less lonely.
- Inclusion of a recent Swiss study that found post-menopausal women were consuming high amounts of vegetables but insufficient amounts of calcium-rich foods (Lanyan & others, 2020)
- New coverage of a recent national study on the sexual activity and sexual health of 65- to 80-year-olds (University of Michigan, 2018)

Chapter 13: Moral Development, Values, and Religion

- Important changes made based on the recommendations of leading experts Daniel Lapsley and Gustavo Carlo
- Significantly revised discussion of Kohlberg's three levels of moral reasoning for greater clarification and accuracy
- Expanded and updated discussion of moral disengagement (Lapsley, LaPorte, & Kelley, 2022)
- Inclusion of recent research documenting the role of moral disengagement in bullying and increases in the bully's aggression (Bijared & others, 2021; Mascia & others, 2021)
- Coverage of a recent study that revealed mothers' mind-mindedness when engaged with their infants was linked to the children's higher level of conscience at 6 years of age (Goffin, Kochanska, & Yoon, 2020)
- Description of a recent study that found a lower level of maternal sensitivity in early childhood was associated with a decrease in children's conscience in early childhood and an increase in conduct problems during the elementary school years (Ettekal & others, 2020)
- Discussion of a recent study in which children and adolescents said that changes in moral beliefs are more disruptive to one's identity than changes in social conventional beliefs (Lefebvre & Krettenaur, 2020). Also in this study, the children and adolescents reported that changes in negative moral beliefs are more disruptive to one's identity than changes in positive moral beliefs.
- New *Connecting with Research* interlude describing how parent and peer relationships influence Latinx adolescents' prosocial behavior
- New main section, "Culture"
- Description of differences in behavior between WEIRD (Western, Educated, Industrialized, Rich, and Democratic) cultures that emphasize individual rights and independent behavior and non-WEIRD cultures that are characterized by duty-based communal obligations and collective, interdependent behavior
- Discussion of differences in morality within a culture, such as behavioral differences between people in lower-SES and higher-SES subgroups
- Inclusion of a recent study of Chinese and Dutch 17- to 26-month-olds in which the toddlers displayed more happiness (smiling more, for example) after sharing treats than after receiving treats (Song, Broekhuizen, & Dubas, 2020)
- Coverage of a recent study in 12 countries that found sharing increased from 4 to 12 years of age in each of the countries (Samek & others, 2020)
- New content on the association of prosocial behavior with other positive aspects of development in adolescence (Donahue, Tillman, & Luby, 2020)
- Inclusion of a recent meta-analysis of 55 studies involving participants from childhood through emerging adulthood that revealed higher levels of prosocial behavior were associated with lower levels of internalizing and externalizing problems (Memmott-Elison & others, 2020)
- Description of a recent study of Chinese adolescents in which empathy played an important role in increasing forgiveness of an offender's transgression (Ma & Jiang, 2020)
- Discussion of a recent study of adolescents that revealed both gratitude and forgiveness were linked to a lower level of reactive and proactive aggression through their connection to self-control (Garcia-Vazquez & others, 2020)
- Inclusion of recent research indicating that other-praising gratitude expressions improve social relationships (Weiss, Burgmer & Lange, 2020)
- Description of recent research that found adolescents with the character strength of gratitude were more likely to

engage in prosocial behavior and to show peer acceptance (Lavy & Benish-Weisman, 2021)

- Discussion of a recent study of U.S. and Japanese middle-aged adults in which higher gratitude was linked to positive psychological functioning and lower gratitude was related to lower psychological functioning (Srirangarajan & others, 2020)
- Coverage of a recent study of older adults that found reflecting more on the important lessons life had taught them increased their forgiveness, which in turn boosted their positive attitudes toward aging, life satisfaction, hope, and self-esteem (Bryant, Osowski, & Smith, 2021)
- Description of a recent study of lesbian and gay older adults that revealed volunteers had better health, more positive mental health, and less psychological distress (Lyons & others, 2021)
- Coverage of recent research indicating that older adults who engage in volunteering have better mental health than their counterparts who don't (Jorgenelis & Pettigrew, 2020)
- Inclusion of a recent national study that revealed adults aged 65 and older were more likely to engage in volunteering than their younger counterparts and also were more likely to report that they volunteer because they want to use their skills and experiences meaningfully (AARP, 2019)
- Inclusion of a recent survey that found 86 percent of college students said they had cheated (Kessler International, 2017)
- Updated data on the percentage of children and youth who have conduct disorder (up to 10 percent) and new data indicating that approximately 25 percent of these individuals subsequently develop antisocial personality disorder (Rubin, 2020)
- Coverage of a British longitudinal study of males from 8 to 61 years of age in which the childhood factors that best predicted which individuals would have criminal careers lasting at least 20 years were harsh discipline, poor parental supervision, parental conflict, and a convicted father (Farrington, 2020)
- Description of the longitudinal Pittsburgh Youth Study that revealed the adolescent factors that best predicted which boys were most likely to be in the worst category of criminal offenders through their thirties were frequency of sexual activity, school problems, and having friends who were a bad influence (Ahonen & others, 2020)
- Discussion of a recent study that found neighborhood poverty was linked to delinquency in adolescence, especially through maternal stress and adverse childhood experiences (Wang, Choi, & Shin, 2020)
- Description of a recent study that revealed parental monitoring was a protective factor against delinquency for both boys and girls, but had a stronger effect for girls than boys (Liu & Miller, 2020)
- Discussion of a recent study that indicated associating with prosocial peers at 12 years of age was linked to decreased drug use and a lower incidence of property-offending delinquency a year later (Walters, 2019)
- Inclusion of a recent research review in which a lack of academic success and having a learning disability were linked to juvenile delinquency (Grigorenko & others, 2019)
- Description of a recent study of 11- to 17-year-olds in which greater school engagement was linked to committing fewer minor offenses as well as fewer crimes against persons and property (Lamari-Fisher & Bond, 2021)
- Coverage of a recent study in rural China that found low self-control was linked to delinquent behavior in adolescents (Jiang, Chen, & Zhuo, 2020)
- Updated content on American college freshmen's views on the importance of being very well-off financially versus developing a meaningful philosophy of life (Stolzenberg & others, 2019)
- New content indicating that a number of studies have found that adolescents who are more religious are more likely to engage in service learning activities (Hart, 2020)
- Updated data on the percentage of adolescents who adopt the same religion as their parents (48 percent) (Diamant & Sciupac, 2020)
- Updated content from a national study on the continuing decline of attendance at religious services by high school seniors (Stolzenberg & others, 2019)
- Coverage of a recent study in which religiosity was linked to a delayed initiation of alcohol use, more so for girls than boys (Barry, Valdez, & Russell, 2020)
- Discussion of a recent Danish study in which participating in a religious organization and praying were associated with fewer risk factors for engaging in an unhealthy lifestyle (Herold & others, 2021)
- Inclusion of a recent study of older adults that revealed those with stronger religiosity were less depressed and had longer telomeres on their chromosomes (Wang & others, 2020)
- Description of a recent survey that found when individuals were asked what gives them a sense of meaning in life, 69 percent said family, 34 percent said career, and 20 percent said spirituality and faith (Pew Research Center, 2018)
- Coverage of recent research indicating that meaning in life can reduce psychological distress (Yu & others, 2020) and facilitate mental health recovery (Jun & Yun, 2020)

Chapter 14: Families, Relationships, and Parenting

- Coverage of a recent study in which destructive marital conflict was linked to less effective coparenting (Kopystynska, Barnett, & Curran, 2020)
- Inclusion of recent national data on the increasing percentage of people in the U.S. who have never married—35 percent of men and 30 percent of women in 2019 compared with 30 percent of men and 23 percent of women in 1990 (U.S. Census Bureau, 2019)
- New data indicating that African American adults (47 percent) are much more likely to be single than non-Latinx White adults (28 percent) and Latinx adults (27 percent) (Brown, 2020)
- Updated data on the increasing percentage of U.S. adults who live in a single person household—36 million in 2019 compared with 7 million in 1960

- Expanded content on the reasons that an increasing percentage of adults are remaining single and never marrying
- Coverage of a recent nationally representative survey of more than 35,000 U.S. single adults that found they are increasingly having uncommitted sexual encounters and taking far longer to make a formal commitment to a partner, a circumstance described as "fast sex and slow love" (Fisher & Garcia, 2019). Nonetheless, in this survey, today's singles show a strong interest in finding romantic love and a partner they can live with forever.
- Updated data on the increasing percentage of emerging and young adults who are cohabiting (U.S. Census Bureau, 2019)
- New content indicating that at lower SES levels, couples are more likely to cohabit and give birth prior to marriage and less likely to marry at all (Karney, 2021)
- New description of the recent U.S. trend of adults engaging in serial cohabitation in the last decade (Eickmeyer & Manning, 2018)
- New content on cohabitation increasing in China and Taiwan but continuing to be rare in Japan and South Korea
- Inclusion of a recent national survey that found married couples reported higher relationship satisfaction than those living with an unmarried partner (Horowitz, Graf, & Livingston, 2019)
- Discussion of a recent study that indicated early transitioning into a stepfamily home, especially for females, was linked to earlier entry into cohabitation (Johnston, Cavanagh, & Crosnoe, 2020)
- New content on cohabitation more often being perceived as a stepping stone to marriage in the United States but more frequently perceived as an alternative to marriage in Europe, especially in Scandinavian countries (Sassler & Lichter, 2020)
- Updated data on the age of first marriage in the United States, which in 2019 was 30 for men and 28 for women, higher than at any previous point in history (U.S. Census Bureau, 2019)
- Coverage of a recent study that found men had a higher level of marital satisfaction than women across a number of countries (Sorokowski, Kowal, & Sorokowska, 2019). In this study, marital satisfaction was similar among Muslims, Christians, and atheists.
- New comparison of age at first marriage in a number of developed countries, with individuals in Sweden getting married latest and those in Israel and Turkey earliest
- Inclusion of a recent study that explored reasons why individuals get married, with love (88 percent of the respondents) at the top of the list (Geiger & Livingston, 2019)
- New discussion of factors such as forgiveness and commitment as indications of whether a marriage is successful (Lavner & Bradbury, 2019)
- Inclusion of a recent study in which couples high in neuroticism were less satisfied with their marriage than those high in conscientiousness (Sayehmiri & others, 2020)
- Coverage of a longitudinal study that revealed hostile marital interactions increased couples' psychological distress, health risk behaviors, and BMI in early middle age, which in turn were linked to greater physical illness later in life (Lee & others, 2021)
- Description of a longitudinal study of middle-aged married adults that found negative behavior in their marriage decreased and positive behavior increased across 13 years in middle age (Verstaen & others, 2020)
- New data on the percentage of U.S. men 65 years of age and older (69 percent) and women in the same age group (47 percent) who were married in 2019 (Administration on Aging, 2020)
- New content and data on the percentages of individuals from different ethnic groups who are married (U.S. Census Bureau, 2019)
- New content and data on the percentages of newlyweds and all married people who are married to someone from a different ethnic group, percentages that have increased dramatically in recent years (Livingston & Brown, 2017)
- Coverage of recent research on Mexican married older adults in which spousal support was associated with less loneliness, while spousal strain was linked to more loneliness three years later (Saenz, 2021)
- Updated data on divorce rates in the United States (U.S. Census Bureau, 2019)
- New content on ethnic variations in divorce rates. Among Latinxs, 30 percent of women and 27 percent of men become divorced in their lifetime.
- Updated data on divorce rates in different countries, with Russia having the highest rate of divorce and Chile the lowest (OECD, 2019)
- Coverage of a recent research review that concluded divorced adults have a higher rate of adverse cardiovascular events, including death due to cardiovascular disease, than their married counterparts (Dhindsa & others, 2019)
- Updated data on the percentage of individuals 65 years of age and older who are divorced, which increased to 15 percent in 2017 (U.S. Census Bureau, 2018)
- Revision and updating of the coverage of marriage and divorce in middle age to account for the recently increasing percentage of middle-aged adults who are getting divorced
- Inclusion of a recent study that indicated today's older adults are more accepting of divorce than their counterparts from two decades ago (Brown & Wright, 2019)
- Updated data on the significant decrease in remarriage that is occurring in the United States (Schweizer, 2019)
- Description of a recent study examining the extent to which men and women repartner following a gray divorce (that is, when they are 50 years of age and older) (Brown & others, 2019). In this study, 22 percent of women and 37 percent of men repartnered following a gray divorce.
- New content on the double retreat in family structure that is taking place in the United states–decline in marriage and decline in remarriage
- Discussion of a recent study in which adults in same-sex relationships experienced similar levels of commitment, satisfaction, and emotional intimacy as their counterparts in different-sex relationships (Joyner, Manning, & Prince, 2019)

- New data on the age of mothers when they have their first child in the United Kingdom, which increased to 30 years of age in 2018, compared with 27 years of age in the United States
- Inclusion of a recent study that revealed higher levels of anxiety and depression in mothers in the last trimester of pregnancy were associated with infants' externalizing problems at 2 years of age, and higher levels of anxiety and depression in fathers in the last trimester of pregnancy were related to higher levels of infants' internalized and externalized problems at 14 months of age (Hughes & others 2020)
- Coverage of a recent study involving the Bringing Home Baby project that found fathers who participated in the program felt more appreciated by their wives and that wives were more satisfied with the division of labor when fathers were more involved in parenting (Shapiro, Gottman, & Fink, 2020)
- Updated data on the age at which U.S. mothers have a first child, which is now at the oldest age ever—26.9 years (National Center for Health Statistics, 2019)
- Discussion of a recent study that revealed when parents had little awareness of their adolescents' whereabouts, adolescents were more likely to smoke cigarettes and initiate smoking at an earlier age (Sartor & others, 2020)
- Inclusion of a recent study in which parental active tracking measures during adolescence and college were associated with better health behavior in both developmental time frames (Abar & others, 2021)
- Discussion of a recent study that revealed authoritarian parenting was associated with being a bully perpetrator in adolescence (Krisnana & others, 2021)
- Coverage of a recent Chinese study that found authoritative parenting increased children's favorable trajectories of math achievement (Want, Chen, & Gong, 2021)
- Description of recent research indicating that authoritative parenting reduced adolescent screen time (Xu, 2021)
- Inclusion of a recent study in which authoritarian parenting was linked to all forms of child maltreatment, while authoritative parenting was associated with a lower risk for all types of child maltreatment (Lo & others, 2019)
- Coverage of recent research with 7- to 9-year-olds that revealed indulgent parenting was associated with increased body mass index (BMI) (Hughes & others, 2021)
- Discussion of a recent study conducted during the COVID-19 pandemic which found that nearly 20 percent of parents had hit or spanked their children in the previous two weeks and indicated that they had increased their use of spanking during those two weeks (Lee & others, 2021)
- Update on the number of countries that ban corporal punishment of children (an increase from 34 in 2012 to 59 in 2020) (Global Initiative to End All Corporal Punishment of Children, 2020)
- New research with college students indicating that daughters are less likely than sons to be punished by both parents (Melhausen-Hassoen & others, 2021)
- Updates on the controversy about whether research adequately documents that physical punishment has detrimental effects on children's development (Gershoff & others, 2019; Larzelere & others, 2019)
- Discussion of recent research in which effective coparenting when children were 3 to 5 years of age was linked to fewer externalizing problems 8 to 10 years later (Parkes, Green, & Mitchell, 2019)
- Coverage of a recent study of low-income, unmarried couples that revealed cooperative coparenting at earlier points in time resulted in fewer child behavior problems (Choi, Parra, & Jiang, 2019)
- Updated data on the extent of child maltreatment in the United States, including new data on specific types of abuse (Administration for Children & Families, 2020)
- Inclusion of recent research that found young children who were abused in the first five years of life were more likely to later receive special education services, to repeat a grade in school, to have been convicted of a crime in the past year, and to have poorer physical health than individuals who had not been abused in early childhood (Lansford & others, 2021)
- Description of a recent research review in which childhood sexual abuse was linked to increased incidence of mental health disorders (including anxiety and mood disorders), as well as substance use disorders (Noll, 2021)
- Discussion of a recent study that revealed parental emotional abuse, more than any other type of abuse, was associated with increased rates of post-traumatic stress disorder in adolescence (Hoeboer & others, 2021)
- Inclusion of a recent large-scale Canadian study in which a history of child maltreatment involving either physical abuse or sexual abuse was linked to having physical and mental health problems in adulthood (Cameranesi, Lix, & Piotrowski, 2019)
- Coverage of a recent study that found child maltreatment was associated with an increase in psychiatric problems and substance abuse in adulthood (Wang & others, 2020)
- Inclusion of a recent study of low-income families revealing that the rate of intergenerational abuse was high and reflected a pathway that increased children's maladaptive socioemotional development (as indicated in emotion dysregulation, for example) (Warmingham, Rogosch, & Cicchetti, 2020)
- Discussion of a recent study that revealed child maltreatment was linked to increased emotion-focused coping and decreased problem-solving coping (VanMeter, Handley, & Cicchetti, 2020)
- Coverage of recent research that found mothers who had experienced child maltreatment from their parents were more likely to engage in maltreatment of their offspring, which in turn was linked to an increased externalizing and internalizing symptoms in late childhood (Russoti & others, 2021)
- Inclusion of a recent large-scale study in which social support and coping skills were linked to positive adult mental health outcomes for maltreated children (Su, D'Arcy, & Meng, 2020)
- Description of a recent study of Lebanese adolescents that found those who were securely attached to their parents had

lower rates of addiction to alcohol and cigarettes than their insecurely attached counterparts (Nakhoul & others, 2020)

- Coverage of a recent study that indicated maltreated and delinquent adolescents had high levels of insecure attachment (Protic & others, 2020)
- Inclusion of a recent Chinese study in which a lower level of parent-adolescent conflict was linked to less adolescent risk-taking (Liu, Wang, & Tian, 2019)
- Discussion of a recent meta-analysis of 54 studies that concluded children who experience parental divorce are at increased risk for depression, anxiety, suicide attempts, distress, alcohol abuse, drugs, and smoking (Auersperg & others, 2019)
- Coverage of a recent study that found adolescents' emotional and behavioral problems increased after their parents divorced, not before (Tullius & others, 2021)
- Discussion of a 15-year longitudinal study of divorced families that involved an 11-session parenting improvement program that had a cascading effect of improved child, adolescent, and adult outcomes (Wolchik & others, 2021)
- Inclusion of recent research indicating that lesbian mothers, heterosexual mothers, and gay fathers reported higher parenting competence than heterosexual fathers (Farr & Vasquez, 2020a)
- Coverage of a U.K. longitudinal study of gay father, lesbian mother, and heterosexual parent families when their children reached early adolescence that found little difference among the three family styles but indicated that better parenting quality and parental mental health were linked to fewer adolescent problems (McConnachie & others, 2021)
- New *Connecting with Research* interlude exploring the roles that school counselors might play in helping transracial adoptees deal with identity issues
- Description of a recent study that indicated birth fathers, who are often less likely to be included in open adoption, would like to be part of the open adoption triad (adoptee, birth family, and adoptive family (Clutter, 2020)
- Update on the significant increase in the number of grandparents alive today in the United States (70 million) (AARP, 2019)
- Coverage of a recent study that found when children live with their grandparents, the arrangement especially benefits low-income and single parents, who are able to spend more money on their children's education and activities and less money on child care (Amorim, 2019)
- Inclusion of a recent Japanese study that revealed caring for at least one co-residing grandchild 6 years of age or younger was neither detrimental nor beneficial to grandparents' health (Oshio, 2021)
- New prediction that in 2030, more than 70 percent of U.S. 8-year-old children will have at least one great-grandparent who is living (AARP, 2019)
- Discussion of a recent study that revealed middle-aged adults were happiest when they had harmonious relationships with their parents and their adult children (Kim & others, 2020)

Chapter 15: Peers and the Sociocultural World

- Coverage of a recent study in the United States and China that found parents' increased peer restriction predicted a decrease in children's adjustment over time (Xiong & others, 2020)
- Inclusion of content indicating that adolescents often rely on peers for emotional support, which was made especially difficult because of the social isolation created by the COVID-19 pandemic (Magson, 2021)
- Description of a longitudinal study that found shyness in childhood predicted lower emotional stability and lower extraversion in adolescence, with these links mainly due to negative peer experiences (Baardstu & others, 2020)
- Discussion of recent research with third- and fourth-graders in which feeling related to peers at school was associated with the children's positive affectivity both at school and at home (Schmidt, Dirk, & Schmiedek, 2019)
- Inclusion of a recent study that found being a fun person to be around was a key component of peer popularity (Laursen & others, 2020)
- Discussion of a recent study in which perceived peer rejection was preceded by either aggression or depression in adolescence (Beeson, Brittain, & Vaillancourt, 2020)
- Coverage of a recent analysis of bullying from 1998 to 2017 in the United States that indicated a significant increase in cyberbullying and face-to-face bullying in females (Kennedy, 2021)
- Description of a recent study of more than 15,000 U.S. high school students that found 20 percent had experienced school bullying and 15 percent had undergone cyberbullying (Webb & others, 2021). In this study, sexual minority adolescents were much more likely to be bullied than were heterosexual adolescents. In addition, African American and Latinx adolescents were less likely to have experienced both types of bullying.
- Inclusion of a recent Chinese study that found adults 60 years of age and older who had experienced bullying victimization as children had more severe depression symptoms than their counterparts who had not been bullied as children (Hu, 2021)
- Discussion of a longitudinal study in which after being bullied, bullying victims' self-esteem decreased and this lower self-esteem was linked with further bullying victimization (Choi & Park, 2021)
- Inclusion of a recent study of more than 150,000 12- to 15-year-olds in low- and middle-income countries that found victims of bullies were characterized by these obesity-related factors: anxiety-induced sleep problems, lack of physical exercise, sedentary behavior, and fast food consumption (Smith & others, 2021)
- Description of a recent large-scale Norwegian study that concluded bullies, victims, and bully-victims are at risk for developing sleep problems, including shorter duration of sleep and higher prevalence of insomnia, as well as lower grade point averages (Hysing & others, 2021)

- New *Connecting with Research* interlude exploring the long-term effects of bullying on children with autism
- Discussion of a recent study of university students in which being a cybervictim increased the risk of suicidal ideation as well as heightened anxiety, stress, and depression (Martinez-Monteagudo & others, 2020)
- Inclusion of a recent study of eighth-graders in which peer pressure was associated with substance use (Jelsma & Varner, 2020)
- Discussion of a recent study that found the Hip Hop crowd and the alternative crowd were at increased risk for a number of negative behaviors (Jordan & others, 2019)
- New content on adolescent social distancing as a consequence of the coronavirus pandemic and recommendations for parental discussions with adolescents regarding safety during the pandemic
- Discussion of research indicating that higher-intensity friendships are likely to amplify an adolescent's pre-existing tendencies toward depression or aggression (Costello & others, 2020)
- New description of a recent study of young adolescents revealing that for non-Latinx White and Asian American adolescents, higher academic achievement was associated with having same-ethnic friends, while for African American and Latinx adolescents, higher academic achievement was linked with having cross-ethnic friends (Chen, Saafir, & Graham, 2020)
- Coverage of a recent study of Saudi Arabian youth that found they had a higher rate of suicidal thoughts and behavior when their friends disclosed depression and self-harm (Copeland & others, 2021)
- Inclusion of a recent study that revealed peers' influence on adolescents' healthy eating behavior is often negative and characterized by increased consumption of energy-dense and low-nutritional-value foods (Rageliene & Granhoj, 2020)
- Description of a recent meta-analytic review that concluded friendship experiences may be more closely related to loneliness than to depressive symptoms (Schwartz-Mette & others, 2020)
- New commentary by Laura Carstensen noting that older adults are less lonely and more happy than young adults
- Coverage of a recent study of older adults in which having a larger friend confidant network or closer connections with friend confidants was linked to better marital quality for wives and husbands 5 years later (Zhaoyang & Martire, 2021)
- Discussion of a recent study of older adults that revealed interactions with friends were more pleasant and were associated with fewer stressful discussions of experiences than interactions with partners or family members (Ng & others, 2020)
- Inclusion of a recent Korean study of 40- to 69-year-olds in which engaging in leisure-time physical activity was linked to a lower risk of death, and those who engaged in vigorous, intense physical activity benefitted the most (Park & others, 2020)
- New description of a recent study that found middle-aged and older adult women who engaged in a higher level of leisure-time physical activity were more likely to report experiencing positive affect (Holahan & others, 2020)
- Inclusion of recent research on middle-aged Europeans indicating that those who engaged in more physical activity during their leisure time were less likely to be depressed (Marques & others, 2020)
- Coverage of recent research in which the more individuals engaged in leisure-time physical activity, the less work-related stress they had (du Prel, Siegrist, & Borchart, 2019)
- Inclusion of a number of changes based on feedback and editing by leading expert Laura Carstensen
- Revised description of social selectivity theory
- Discussion of a recent research review of older adults' health that concluded ageism led to worse health outcomes, especially in less-developed countries and among those with less education (Chang & others, 2020)
- Description of a recent analysis which concluded that the COVID-19 pandemic brought a parallel increase in ageism, with increased views of older adults as being helpless, frail, and unable to contribute to society (Ayalon & others, 2021)
- Inclusion of a recent meta-analysis of Chinese older adults in which having a low level of social support was linked to depression and increased social support was associated with reduced depression (Qui & others, 2020)
- Coverage of a recent study in which being lonelier and less socially integrated were linked to increased suicidal ideation in single older adult men (Lutzman, Sommerfeld, & Ben-David, 2021)
- Discussion of a recent study of older adults that revealed interacting with a greater variety of social ties was related to engaging in more physical activity and less sedentary behavior (Fingerman & others, 2020). Also in this study, greater involvement with diverse social ties was associated with being in a more positive mood.
- Expanded coverage of what the term *culture* means, including content on how everyone has a culture (with multiple examples provided)
- Inclusion of a recent study of Japanese elementary school children that revealed greater screen time duration was linked to increased obesity, decreased physical activity, and lower academic performance (Mineshita & others, 2021)
- Coverage of a recent Dutch study indicating that children's physical activity was lower and their screen time was much higher during and after school closures due to the COVID-19 pandemic lockdown (Ten Velde & others, 2021)
- Description of World Health Organization (WHO) recommendation that 3- to 4-year-old children should engage in no more than 1 hour of screen time daily (Willumsen & Bull, 2020)
- Inclusion of recent research on 13- to 18-year-olds in the United States and the United Kingdom that found significant gender differences in the types of digital media they used (Twenge & Martin, 2020)
- Coverage of a recent study of 11,000 9- and 10-year-olds that found screen time was linked to reduce sleep duration,

later sleep onset, and more sleep disturbances (Hisler & others, 2020)

- Description of a recent study that revealed screen media multitasking at 18 months of age was linked to having more behavioral problems and lower cognitive functioning at 4 to 6 years of age (Srisinghasongkram & others, 2021)
- Update on the percentage of adolescents who own a smartphone, which increased from 66 percent in 2009 to 95 percent in 2018 (Anderson & Jiang, 2018)
- Inclusion of a 2019 survey indicating the percentage of 18- to 24-year-olds who were using YouTube (90 percent), Facebook (76 percent), Instagram (75 percent), and Snapchat (73 percent) (Perrin & Anderson, 2019)
- Discussion of a recent large-scale study of more than 32,000 15-year-olds in 37 countries that found problematic social media use and low social support were the best predictors of low life-satisfaction (Walsh & others, 2020)
- Description of a recent national survey in 2019 of the percentage of U.S. older adults age 65 and over who use the Internet (73 percent) (Anderson, 2019)
- Inclusion of a recent study of older adults that revealed increased Internet use was linked to decreased loneliness (Yu, Wu, & Chi, 2021)
- Coverage of a recent study in which lower SES was linked to less cortical surface area in the brain of adolescents as well as less effective working memory (Judd & others, 2020). The SES factor most responsible for the lower level of brain functioning was less parental education.
- Inclusion of a recent Chinese study that found low family SES was linked to children's low academic achievement, being especially influenced by lower parental involvement in children's schooling (Zhang & others, 2020)
- Updated data on the percentage of U.S. adults below the poverty line with varying degrees of education (Duffin, 2019)
- Updated data on the percentage of single-mother families living in poverty (34 percent), which was nearly five times as high as their married counterparts (6 percent) (U.S. Census Bureau, 2019)
- Inclusion of a recent study of older adults that found poverty was a risk factor for earlier death (Guimaraes & Andrade, 2020)
- New opening commentary in the section on Ethnicity focused on the importance of not using a deficit model in studying ethnic minority adolescents and recognizing not just stressors in their lives but also the positive aspects of their lives (Weissmark & others, 2020)
- Updated data on the percentage of children 18 years old and younger from different ethnic groups in the United States (U.S. Census Bureau, 2018)
- New discussion of research by Yoonsun Choi and her colleagues (Choi & Hahn, 2017; Choi & others, 2020a, b, c) on generational differences in Filipino Americans and Korean Americans, as well as younger Asians' belief that older Asians place too much emphasis on education
- Coverage of a recent study in which immigrant children who were separated from their parents had a lower level of literacy and a higher level of psychological problems than those who migrated with their parents (Lu, He, & Brooks-Gunn, 2020). Also in this study, a protracted period of separation and prior undocumented status of parents further increased the children's disadvantages.
- New content on multi-ethnic/racial individuals and the discrimination they often encounter (Tan & others, 2019; Woo & others, 2020)
- New description of the positive outcomes when adolescents have a positive ethnic identity (Umaña-Taylor & others, 2020)
- New discussion of a recent study in which Latinx adolescents showed enhanced resilience against discrimination encounters when they had more family ethnic socialization experiences and greater engagement in identity exploration and resolution (Martinez-Fuentes, Jager, & Umaña-Taylor, 2021)
- New main section, "Racism and Discrimination"
- New coverage of the Black Lives Matter movement and the killing of George Floyd in Minneapolis as well as discussion of past and current racism and discrimination in the United States
- New discussion of how to talk with children about racism based on the Intentional Parenting for Equity and Justice program proposed by Diane Hughes and her colleagues (Hughes, Fisher, and Cabrera, 2020)
- Inclusion of new content based on BIPOC (Black, Indigenous, and other People of Color) parents' emphasis on how their children and youth can stay safe during interactions with the police
- Recommendation of a recent book that helps BIPOC parents talk with their children and youth about race: *The ABCs of Survival* (National Black Child Family Institute, 2021)
- New content on the dramatic increase in ethnic diversity that is predicted to occur for older adults (U.S. Census Bureau, 2019)
- New data on poverty rates for African American older adults, which have declined since 1975 but are still far too high (Congressional Research Service, 2019)

Chapter 16: Schools, Achievement, and Work

- New commentary noting that the federal government suspended standardized testing in schools in 2020 because of the coronavirus pandemic
- Update on the number of Montessori schools in the United States and around the world in 2021 (National Center for Montessori in the Public Sector, 2021)
- New coverage of an experimental study with young children in a high-poverty area which found that over a 3-year period those who attended Montessori programs fared better in academic achievement, social understanding, and mastery orientation than those who attended other early childhood programs (Lillard & others, 2017)
- Inclusion of a recent study in which young children who attended Montessori schools displayed better creativity skills

than their counterparts in traditional schools (Denervaud & others, 2019)

- Description of a recent study in which a social-emotional learning program and a coordinated interactive reading program were used to enrich Head Start classrooms, an intervention that resulted in the children having significantly fewer conduct problems and negative emotional symptoms, as well as better peer relations in adolescence (Bierman & others, 2021)
- Coverage of a recent study of 3- to 4-, 5- to 6-, and 8- to 9-year-olds that found children in foster care who participated in Head Start programs had better cognitive, socioemotional, and health outcomes than their foster care counterparts who did not attend Head Start programs (Lee, 2020)
- Discussion of a recent study that revealed increased teacher-student conflict during the transitions from elementary school to middle school and middle school to high school were linked to an increased externalizing symptoms in the students' first year at the new school (Longobardi & others, 2019)
- Inclusion of a recent study in which students in the first year of middle school had lower levels of adaptive coping and higher levels of maladaptive coping than elementary school students did (Skinner & others, 2020)
- Updated data on school dropout rates, which continue to decline considerably (National Center for Education Statistics, 2020)
- Updated data on the transition to college, with a much higher percentage of first-year college students today saying they feel overwhelmed with all they have to do (Stolzenberg & others, 2020)
- Updated data on the percentage of children with a disability receiving special education services in different disability categories (National Center for Education Statistics, 2020)
- Coverage of recent research that found African American children and adolescents are more likely to be diagnosed with ADHD than their non-Latinx White and Latinx counterparts (Zablotsky & Alford, 2020)
- Inclusion of recent research suggesting that African American and Latinx children and adolescents are more likely than their non-Latinx White counterparts to be diagnosed with disruptive behavior disorders (Fadus & others, 2020)
- Description of recent research in which preterm birth was linked to ADHD (Walczak-Kozlowska & others, 2020)
- Coverage of recent research indicating that low socioeconomic status is linked to the development of ADHD and also that low SES is associated with inferior brain functioning (Machlin, McLaughlin, & Sheridan, 2020)
- Inclusion of content indicating that the neurotransmitter GABA is linked to the development of ADHD (Puts & others, 2020)
- Description of a research review of meta-analyses and randomized experiments that concluded neurofeedback has medium to large effects on ADHD, with 32 to 47 percent remission rates lasting from 6 to 12 months (Arns & others, 2020)
- Inclusion of an extensive set of meta-analyses that concluded neurofeedback is effective in reducing inattentiveness in children with ADHD but that stimulant medication is more effective than neurofeedback in doing so (Riesco-Matias & others, 2021)
- Coverage of a recent meta-analysis that found regular exercise was more effective than neurofeedback, cognitive training, and cognitive therapy in treating ADHD (Lambez & others, 2020)
- Description of a recent study that revealed children with ADHD were 21 percent less likely to engage in regular exercise than children who had not been diagnosed with ADHD (Mercurio & others, 2021)
- Substantial revision of the discussion of autism spectrum disorders (ASD)
- New content on the dramatic increase in the percentage of children who are autistic (Centers for Disease Control and Prevention, 2020) and the percentage of autistic children who are receiving special education services (National Center for Education Statistics, 2020)
- Discussion of a recent research summary that concluded key early warning signs for ASD are lack of social gestures at 12 months, using no meaningful words at 18 months, and having no interest in other children or no spontaneous two-word phrases at 24 months (Tsang & others, 2019)
- New main section, "Schools and the Coronavirus Pandemic," with separate subsections on K-12 education and college education
- Description of recent research indicating that too often schools were leaving learning to chance for students following the change to online instruction after the coronavirus abruptly shut down in-person classes in 2020 (Gross, 2020)
- Inclusion of a recent study documenting significantly low math achievement scores for students after instruction went online during the pandemic (Chetty & others, 2020)
- New *Connecting with Research* interlude exploring how parental expectations might influence Black boys' math scores
- New discussion exploring whether peer mindsets can influence a student's mindset (Sheffler & Chenug, 2020), including description of a recent study across most of a school year that found students who were around peers with a growth mindset for 7 months increased their growth mindset across that time frame (King, 2020)
- Inclusion of recent research indicating that engaging in a strategic mindset was critical in achieving goals (Chen & others, 2020). College students with a strategic mindset used more metacognitive strategies and in turn had higher grade point averages and made greater progress toward their professional, educational, and health goals.
- New content on David Yeager and his colleagues' (Yeager, Dahl, & Dweck, 2018) national experimental study—a brief, online, direct-to-student growth mindset intervention that increased the grade point averages of underachieving students and also improved the challenge-seeking mental activity of higher-achieving students. In other recent research, the positive outcomes of the U.S. online growth mindset intervention were replicated with students in Norway (Bettinger & others, 2018).

- Inclusion of recent research that revealed a higher level of grit predicted better outcomes in stronger postsecondary institutions that provided better student support, especially in achieving on-time graduation (Goyer, Walton, & Yeager, 2021)
- New list of questions to help students assess how much grit they have (Clark & Malecki, 2019)
- New coverage of the very positive job outlook for college graduates at the beginning of 2020 that turned steeply downward in March and April of 2020 with the onset of the coronavirus pandemic (NACE, 2020)
- Inclusion of the 2019 Trends in International Mathematics and Science Study (TIMSS) of math and science achievement in a number of countries, with East Asian countries taking 19 of the top five spots in fourth- and eighth-grade science and fourth- and eighth-grade math. Singapore was number one in three of the four comparisons.
- Update on the percentage of full-time and part-time students who are working while going to college (National Center for Education Statisics, 2018)
- New content on the major change in the context of work that was mandated by the onset of the coronavirus pandemic, when huge numbers of employees abuptly switched from working in an office, school, or other context to working at home
- Discussion of a Finnish study indicating that alcohol-related death was elevated 0 to 5 and 11 to 20 years after the onset of unemployment (Junna, Moustgaard, & Martikainen, 2021)
- Updated information about the fastest-growing jobs anticipated through 2028 in the 2020–2021 *Occupational Outlook Handbook*
- Coverage of a recent study in which work-related stress and night-shift work increased workers' obesity (da Silva & others, 2021)
- Description of a recent study in 15 European countries that found work stress increased from 1995 to 2015, especially in lower-skilled occupations (Rigo & others, 2021)
- New content on the extensive increase in unemployment that occurred in 2020 because of the coronavirus pandemic
- Inclusion of a recent study that found more mothers than fathers were dissatisfied with their work-family balance and partner's share of family responsibilities before the COVID-19 pandemic (Craig & Churchill, 2020). For some, the pandemic improved satisfaction levels, but for most they became worse.
- Updated data on the percentage of U.S. 45- to 54- and 55- to 64-year-olds in the workforce, including comparisons of 2019 to 2015 and 2000 (Mislinski, 2019)
- New coverage of the percentage of individuals 65 to 69 years of age who are still working in the United States and in other countries, with the highest percentage being in Asian countries and the lowest in European countries (McCarthy, 2019)
- Discussion of a recent analysis indicating that healthier, higher-income, and better-educated older adults can continue working longer than lower-income older adults whose jobs are physically demanding (United Income, 2019)
- Inclusion of recent findings that indicate older workers are more satisfied at work, take fewer sick days, and demonstrate stronger problem-solving skills than younger workers (Milken Institute and Stanford Center of Longevity, 2019)
- New description of a recent analysis of U.S. workers in which more than 50 percent of those 50 years and older are pushed out of long-time jobs before they choose to retire (Gosselin, 2019)
- Inclusion of a recent report indicating that 37 percent of individuals in the United States retire earlier than they had planned (Munnell, Rutledge, & Sanzenbacher, 2018)
- Discussion of a recent study that found all retirement pathways were associated with cognitive decline for workers in low-complexity jobs but were not linked to accelerated cognitive decline for those in high-complexity jobs (Carr & others, 2020). Also, after retiring and subsequently returning to work, a modest improvement in cognitive function occurred.
- Inclusion of a recent study that revealed retirement satisfaction was linked to carrying out retirement plans, possessing resilience, achieving social integration, adopting new roles, and maintaining quality family relationships (Principi & others, 2020)
- Coverage of recent research in European countries indicating that memory decline accelerated after retirement (Macken, Riley, & Glymour, 2021)

Chapter 17: Death, Dying, and Grieving

- New commentary noting that the extensive number of deaths due to the coronavirus pandemic is making many Americans more aware of death than in recent decades
- Addition of the view of some critics that completion of a living will creates the potential for premature withdrawal of interventions (Kurin & Mirachi, 2021)
- Update on Physician Orders for Life-Sustaining Treatment (POLST), which in 2019 was available in 40 states
- Update on the number of states that allow assisted suicide, which recently increased to 9 states plus Washington, DC
- Update on countries that allow assisted suicide and those that allow both assisted suicide and euthanasia
- New content based on a national study of 10- to 19-year-olds indicating that suicide rates for males and females have increased since 2007, with a disproportionate, steeper increase among 10- to 14-year-old females (Ruch & others, 2019)
- New content indicating that suicide has replaced homicides as the second leading cause of death in adolescence (National Center for Health Statistics, 2020)
- Updated data on the percentage of U.S. adolescents who seriously consider suicide each year and attempt suicide each year, including gender and ethnicity figures (Underwood & others, 2020)
- Cross-cultural comparisons of adolescent suicide

- Discussion of a recent study of adolescents in Hong Kong that found suicide attempts were linked to a history of child abuse (Wong & others, 2020)
- Inclusion of a recent study of 9- to 10-year-olds in which family conflict was linked to increased suicidal ideation and low parental monitoring was linked to both suicidal ideation and attempts (DeVille & others, 2020)
- Coverage of a recent study in which combined school difficulties (academic failure and inappropriate behavior) were associated with higher suicide risk (Ligier & others, 2020)
- Description of recent research with more than 290,000 adolescents across a four-year period that revealed the highest stressor for suicidal ideation was peer conflict followed by family circumstances, such as conflict with parents (Kim, 2021)
- Inclusion of a recent research review that described the most significant risk factors for adolescent suicide and bullying (Cuesta & others, 2021)
- Discussion of a recent study that found in 32 of 38 countries assessed, early sexual intercourse (at 12 to 15 years of age) was linked to increased suicide attempts and having sexual intercourse with multiple partners increased the risk further (Smith & others, 2020)
- Description of a recent analysis that revealed the main factor in adolescent suicidal deaths was the occurrence of recent stressful life events (Werbart Tomblom & others, 2020)
- Updated data on suicide in adults, with a 35 percent increase occurring from 1999 to 2018 (National Center for Health Statistics, 2020)
- Updated data on gender and ethnic differences in adult suicides, with males and Native Americans/Alaska Natives having the highest suicide rates (National Center for Health Statistics, 2020)
- New content on prolonged grief disorder recently being included in the International Classification of Diseases (ICD-11) as a new mental health disorder (Stelzer & others, 2020)
- Discussion of a recent German study in which difficulties in accepting the loss of a loved one was the most frequent symptom linked to prolonged grief disorder (Rosner & others, 2021)
- Coverage of a recent study in which meaning was negatively associated with depression but positively linked to grief in suicide survivors (Scharer & Hibberd, 2020)
- Inclusion of a recent study examining the first two years of bereavement for family caregivers of terminally ill cancer patients that revealed prolonged grief disorder preceded the onset of major depressive disorder (Tsai & others, 2020)
- Description of a recent research review that concluded the death of an only child and violent killings were most likely to be associated with prolonged grief disorder (Djelantik & others, 2020)
- New content on how the death of individuals due to the coronavirus pandemic and the changes in funeral services due to social distancing policies have produced disenfranchised grief, as only a small number of people can be present at death rituals and spiritual ceremonies, which can make it difficult to mourn the death adequately and lead to greater depression and stress (Albuquerque, Teixeira, & Rocha, 2021; Moore & others, 2020)
- Discussion of a recent research review that concluded the dual-process model provides an accurate representation of the bereavement experience and is effective in describing how individuals cope (Fiore, 2020)
- Inclusion of recent research that found individuals who had a first-degree relative who died suddenly were at increased risk for suicide (Hamdan & others, 2020)
- Update on the percentages of individuals 65 years of age and older in the United States who are widowed: 31 percent of women and 11 percent of men (Administration on Aging, 2021)
- Discussion of a recent analysis that indicated a spouse's death impacted women and men differently (Streeter, 2020). In this study, following spousal death women's income deteriorated while men's emotional and mental health worsened but their financial status remained stable.
- Coverage of a recent study of widows' and widowers' mental health coping strategies in which widows were more likely to use positive reframing, active distraction, help-seeking, and turning to God for strength, while widowers were more likely to use avoidant strategies and seek connection with their late spouse (Carr, 2020)
- Inclusion of a recent research review of widowed Latinxs that found risk factors for diminished well-being were being a man, undergoing financial strain, dealing with cultural stressors, having an undocumented legal status, experiencing widowhood at a younger age, and having poor physical health (Garcini & others, 2021)
- New *Connecting with Research* interlude exploring the ways in which adjustment differs for young and middle-aged adults who lose a life partner
- Updated data on cremation, including continuing increases in cremation in the United States and Canada (Cremation Association of North America, 2020)

acknowledgments

I very much appreciate the support and guidance provided to me by many people at McGraw Hill. Ryan Treat, Senior Portfolio Manager for Psychology, has provided excellent guidance, vision, and direction for this edition. Vicki Malinee provided considerable expertise in coordinating many aspects of the editorial process. Janet Tilden again did an outstanding job as the text's copy editor. Mary Powers did a terrific job in coordinating the text's production. Dawn Groundwater, Product Development Manager, did excellent work on various aspects of the development, technology, and learning systems. Thanks also to Olivia Kaiser for her extensive and outstanding work in marketing *A Topical Approach to Life-Span Development*. And Jennifer Blankenship again has provided me with excellent choices of new photographs.

I also want to thank my parents, John and Ruth Santrock, my wife, Mary Jo, our children, Tracy and Jennifer, and our grandchildren, Jordan, Alex, and Luke, for their wonderful contributions to my life and for helping me to better understand the marvels and mysteries of life-span development.

QUEST: JOURNEY THROUGH THE LIFESPAN BOARD OF ADVISORS AND SUBJECT MATTER EXPERTS

Admiration and appreciation go to the following experts who have devoted a significant portion of their time and expertise to creating the first of its kind learning game for Developmental Psychology: Cheri Kittrell, *State College of Florida*; Brandy Young, *Cypress College*; Becky Howell, *Forsyth Technical College*; Gabby Principe, *College of Charleston*; Karen Schrier Shaenfield, *Marist College*; Steven Prunier, *Ivy Tech*; Amy Kolak, *College of Charleston*; Kathleen Hughes Stellmach, *Pasco-Hernando State College*; Lisa Fozio-Thielk, *Waubonsee Community College*; Tricia Wessel-Blaski, *University of Wisconsin-Milwaukee*, *Washington County*; Margot Underwood, *Joliet Junior College*; Claire Rubman, *Suffolk County Community College*; Alissa Knowles, *University of California-Irvine*; Cortney Simmons, *University of California-Irvine*; Kelli Dunlap; Level Access-WCAG Accessibility Partners.

EXPERT CONSULTANTS

As I develop a new edition, I consult with leading experts in their respective areas of life-span development. Their invaluable feedback ensures that the latest research, knowledge, and perspectives are presented. Their willingness to devote their time and expertise to this endeavor is greatly appreciated. The Expert Consultants who contributed to this edition can be found on pages xix to xxi.

Special thanks also go to Germine Awad, *University of Texas-Austin*; Kevin Cokley, *University of Texas-Austin*; and Sabra Katz-Wise, *Harvard University*.

REVIEWERS

With my appreciation, thank you to those reviewers who provided valuable guidance on issues of inclusion and diversity: Oritsegbubemi Ayu, *Howard University*; Kimberly Boyd, *Virginia State University*; Renia Brown-Cobb, *Virginia State University*; Bernice Carson, *Virginia State University*; Joy Cooley-Doles, *Norfolk State University*; Rene Hernandez, *North Central Texas College*; Amy Osmon, *Daytona State College*; Kimberly Paul, *Southeast Community College*; Michael Reed, *Hampton University*; Erica Russell, *Norfolk State University*; Katrina Walker, *Virginia State University*.

I owe a special debt of gratitude to the reviewers who have provided detailed feedback on *A Topical Approach to Life-Span Development* over the years.

section one

The Life-Span Perspective

Our focus in this course is on human development—its universal features, its individual variations, its nature. Every life is distinct, a new biography in the world. Examining the shape of life-span development allows us to understand it better. *A Topical Approach to Life-Span Development* is about the rhythm and meaning of people's lives, about turning mystery into understanding, and about weaving a portrait of who each of us was, is, and will be. In Section 1, you will read the chapter titled "Introduction."

All the world's a stage,
And all the men and women merely players;
They have their exits and their entrances,
And one man in his time plays many parts.

—**William Shakespeare**
English Playwright, 17th Century.

chapter 1

INTRODUCTION

chapter **outline**

1 The Life-Span Perspective

Learning Goal 1 Discuss the distinctive features of a life-span perspective on development.

The Importance of Studying Life-Span Development
Characteristics of the Life-Span Perspective
Some Contemporary Concerns

2 The Nature of Development

Learning Goal 2 Identify the most important processes, periods, and issues in development.

Biological, Cognitive, and Socioemotional Processes
Periods of Development
The Significance of Age
Developmental Issues

3 Theories of Development

Learning Goal 3 Describe the main theories of human development.

Psychoanalytic Theories
Cognitive Theories
Behavioral and Social Cognitive Theories
Ethological Theory
Ecological Theory
An Eclectic Theoretical Orientation

4 Research on Life-Span Development

Learning Goal 4 Explain how research on life-span development is conducted.

Methods for Collecting Data
Research Designs
Time Span of Research
Conducting Ethical Research
Minimizing Bias

preview

A Topical Approach to Life-Span Development **is a window into the journey of human development—your own and that of every other member of the human species. Every life is distinct, a new biography in the world. Examining the shape of life-span development helps us to understand it better. In this chapter, we explore what it means to take a life-span perspective on development, examine the nature of development, discuss theories of development, and outline how science helps us to understand it.**

1 The Life-Span Perspective

LG1 Discuss the distinctive features of a life-span perspective on development.

The Importance of Studying Life-Span Development

Characteristics of the Life-Span Perspective

Some Contemporary Concerns

Each of us develops partly like all other individuals, partly like some other individuals, and partly like no other individuals. Most of the time, our attention is directed to an individual's uniqueness. But as humans, we have all traveled some common paths. Each of us—Leonardo da Vinci, Joan of Arc, George Washington, Martin Luther King, Jr., and you—walked at about 1 year, engaged in fantasy play as a young child, and became more independent as a youth. Each of us, if we live long enough, will experience hearing problems and the death of family members and friends. This is the general course of our **development**—the pattern of movement or change that begins at conception and continues through the human life span.

development The pattern of movement or change that begins at conception and continues through the human life span.

In this section, we explore what is meant by the concept of development and why the study of life-span development is important. We outline the main characteristics of the life-span perspective and discuss various sources of contextual influences. In addition, we examine some contemporary concerns in life-span development.

THE IMPORTANCE OF STUDYING LIFE-SPAN DEVELOPMENT

How might people benefit from examining life-span development? Perhaps you are, or will be, a parent or a teacher. If so, responsibility for children is, or will be, a part of your everyday life. The more you learn about them, the better you can deal with them. Perhaps you hope to gain some insight about your own history—as an infant, a child, an adolescent, or an adult. Perhaps you want to know more about what your life will be like as you move through the adult years—as a middle-aged adult or as an adult in old age, for example. Or perhaps you have just stumbled upon this course, thinking that it sounded intriguing and that the study of the human life span might raise some provocative issues. Whatever your reasons, you will discover that the study of life-span development is filled with intriguing information about who we are, how we came to be this way, and where our future will take us.

Most development involves growth, but it also includes decline and dying. In exploring development, we examine the life span from the point of conception until the time when life—at least, life as we know it—ends. You will see yourself as an infant, as a child, and as an adolescent, and be stimulated to think about how those years influenced the kind of individual you are today. And you will see yourself as a young adult, as a middle-aged adult, and as an adult in old age, and be motivated to think about how your experiences today will influence your development through the remainder of your adult years.

> One's children's children's children: Look back to us as we look to you; we are related by our imaginations. If we are able to touch, it is because we have imagined each other's existence, our dreams running back and forth along a cable from age to age.
>
> —Roger Rosenblatt
> *American Writer, 20th Century*

CHARACTERISTICS OF THE LIFE-SPAN PERSPECTIVE

Although growth and development are dramatic during the first two decades of life, development is not something that happens only to children and adolescents (Farrell & others, 2021; Small, 2020). The traditional approach to the study of development emphasizes extensive

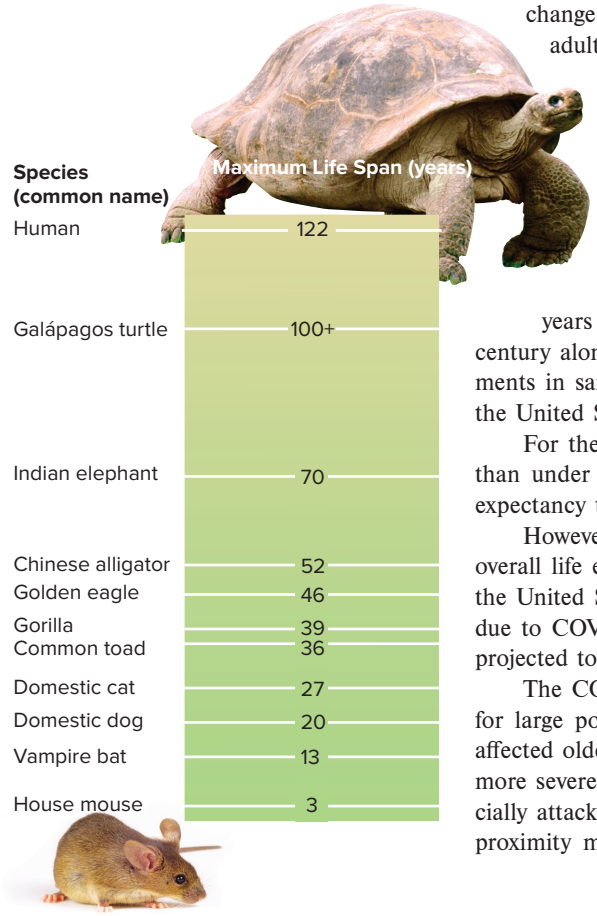

FIGURE 1

MAXIMUM RECORDED LIFE SPAN FOR DIFFERENT SPECIES. Our only competitor for the maximum recorded life span is the Galápagos turtle.

(tortoise): Philip Coblentz/MediaImages/SuperStock; *(mouse)*: Redmond Durrell/Alamy Stock Photo

change from birth to adolescence (especially during infancy), little or no change during adulthood, and decline in old age. But a great deal of change does occur in the five or six decades after adolescence. The life-span perspective emphasizes developmental change throughout adulthood as well as during childhood (Parra-Rizo & Sanchis-Soler, 2020; Saul & Kosinsky, 2021).

The recent increase in human life expectancy has contributed to the popularity of the life-span approach to development. The upper boundary of the human life span (based on the oldest age documented) is 122 years, as indicated in Figure 1; this maximum life span of humans has not changed since the beginning of recorded history. What has changed is *life expectancy:* the average number of years that a person born in a particular year can expect to live. During the twentieth century alone, life expectancy in the United States increased by 30 years, thanks to improvements in sanitation, nutrition, and medicine (see Figure 2). For individuals born in 2017 in the United States, their life expectancy is 78.6 years of age (Arias & Xu, 2019).

For the first time in U.S. history, in 2019 there were more people over 60 years of age than under 18 years of age. In less than a century, more years were added to human life expectancy than in all of the prior millennia.

However, because of the staggering number of deaths due to the COVID-19 pandemic, overall life expectancy projections in 2020 call for a reduction of approximately one year in the United States (Andrasfay & Goldman, 2021). With a disproportionate number of deaths due to COVID-19 occurring among African Americans and Latinxs, their life expectancy is projected to decrease as much as three to four times as much as for non-Latinx Whites.

The COVID-19 pandemic has disrupted our daily lives and created high levels of stress for large portions of the population (Jowell, Carstensen, & Barry, 2020). The disease has affected older adults more than any other age group, with people 65 years of age contracting more severe and deadly versions of COVID-19 than younger individuals. The pandemic especially attacked older adults living in nursing homes and assisted living facilities because their proximity made them highly vulnerable to transmitting the disease to each other. Another

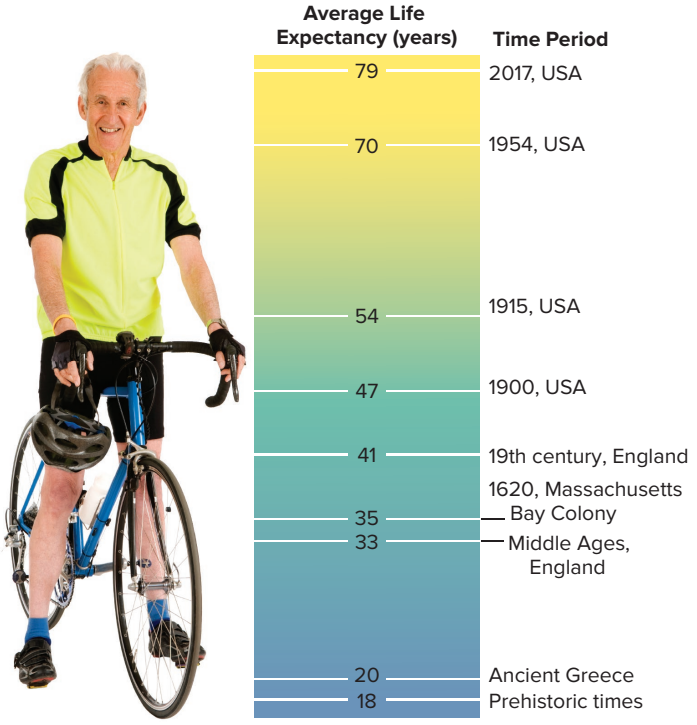

FIGURE 2

HUMAN LIFE EXPECTANCY AT BIRTH FROM PREHISTORIC TO CONTEMPORARY TIMES. It took 5,000 years to extend human life expectancy from 18 to 41 years of age.

leezsnow/iStock.com

vulnerability of older adults in regard to COVID-19 is the loneliness and anxiety associated with isolation from family and friends due to social-distancing requirements.

Laura Carstensen (2015, 2019) recently described the challenges and opportunities involved in this dramatic increase in life expectancy. In her view, the remarkable increase in the number of people living into old age has happened in such a short time that science, technology, and social expectations have not kept pace. She proposes that the challenge is to change from a world constructed mainly for young people to a world that is more compatible and supportive for the increasing number of people living to age 100 and beyond.

In further commentary, Carstensen (2015, p. 70) remarked that making this transformation would be no small feat:

> . . . parks, transportation systems, staircases, and even hospitals presume that the users have both strength and stamina; suburbs across the country are built for two parents and their young children, not single people, multiple generations or elderly people who are not able to drive. Our education system serves the needs of young children and young adults and offers little more than recreation for experienced people.
>
> Indeed, the very conception of work as a full-time endeavor ending in the early sixties is ill suited for long lives. Arguably the most troubling is that we fret about ways the older people lack the qualities of younger people rather than exploit a growing new resource right before our eyes: citizens who have deep expertise, emotional balance, and the motivation to make a difference.

How has the COVID-19 pandemic affected the lives of older adults?
Douglas R. Clifford/Alamy Stock Photo

The belief that development occurs throughout life is central to the **life-span perspective** on human development, but this perspective has other characteristics as well. According to life-span development expert Paul Baltes (1939–2006), the life-span perspective views development as lifelong, multidimensional, multidirectional, plastic, multidisciplinary, and contextual, and as a process that involves growth, maintenance, and regulation of loss (Baltes, 1987, 2003; Baltes, Lindenberger, & Staudinger, 2006). In Baltes' view, it is important to understand that development is constructed through biological, sociocultural, and individual factors working together. Let's look at each of these characteristics.

life-span perspective View of development as being lifelong, multidimensional, multidirectional, plastic, multidisciplinary, and contextual; involving growth, maintenance, and regulation of loss; and constructed through biological, sociocultural, and individual factors working together.

Development Is Lifelong In the life-span perspective, early adulthood is not the endpoint of development; rather, no age period dominates development. Researchers increasingly study the experiences and psychological orientations of adults at different points in their lives. Later in this chapter, we consider the age periods of development and their characteristics.

What characterizes the life-span perspective on development?
lisegagne/Getty Images

Development Is Multidimensional At every age, your body, your mind, your emotions, and your relationships change and affect each other. Development has biological, cognitive, and socioemotional dimensions (Atherton, Donnellan, & Roberts, 2021; Cowan & Smith, 2021; Robertson & Dockree, 2020). Within each of these dimensions are many components—for example, attention, memory, abstract thinking, speed of processing information, and social intelligence are just a few of the components of the cognitive dimension.

Development Is Multidirectional Throughout life, some dimensions or components of a dimension expand and others shrink (Finkel, Bravell, & Pedersen, 2020; Frankenberg, 2021). For example, when one language (such as English) is acquired early in development, the capacity for acquiring second and third languages (such as Spanish and Chinese) decreases later in development, especially after early childhood (Levelt, 1989). During adolescence, as individuals establish romantic relationships, their time spent with friends may decrease. During late adulthood, older adults might become wiser by calling on past experience to guide their intellectual decision making (Howell & Peterson, 2020), but they perform more poorly on tasks that require speed in processing information (Vonk & others, 2020).

Development Has Plasticity Developmentalists debate how much *plasticity* people have in various dimensions at different points in their development (Esteves & others, 2021; Stuss & Craik, 2020). Plasticity means the capacity for change. For example, can you still improve your intellectual skills when you are in your seventies or eighties? Or might these intellectual skills be fixed by the time you are in your thirties, so that further improvement is impossible? Researchers have found that the cognitive skills of older adults can be improved through training and development of better strategies (Hinault & Lemaire, 2020; Wu & others, 2021). However, possibly we possess less capacity for change when we become old (Salthouse,

Paul Baltes, a leading architect of the life-span perspective of development, converses with one of the long-time research participants in the Berlin Aging Study that he directs. She joined the study in the early 1990s and has participated six times in extensive physical, medical, psychological, and social assessments. In her professional life, she was a practicing physician.
©Margaret M. and Paul B. Baltes Foundation

2019). The search for plasticity and its constraints is a key element on the contemporary agenda for developmental research (Anderson & Winocur, 2020; Jiang & others, 2021).

Developmental Science Is Multidisciplinary Psychologists, sociologists, anthropologists, neuroscientists, and medical researchers all share an interest in unlocking the mysteries of development through the life span. How do your heredity and health limit your intelligence? Do intelligence and social relationships change with age in the same way around the world? How do families and schools influence intellectual development? These are examples of research questions that cut across disciplines.

Development Is Contextual All development occurs within a context, or setting. Contexts include families, neighborhoods, schools, peer groups, work settings, churches, university laboratories, cities, countries, and so on. Each of these settings is influenced by historical, economic, social, and cultural factors (Ozdemir, Ozdemir, & Boersma, 2021; Parke & Elder, 2020).

Contexts, like individuals, change (Bornstein & Esposito, 2021). Thus, individuals are changing beings in a changing world. As a result of these changes, contexts exert three types of influences (Baltes, 2003): (1) normative age-graded influences, (2) normative history-graded influences, and (3) nonnormative or highly individualized life events. Each type of influence can have a biological or an environmental impact on development.

normative age-graded influences Influences that are similar for individuals in a particular age group.

Normative age-graded influences are similar for individuals in a particular age group. These influences include biological processes such as puberty and menopause. They also include sociocultural or environmental processes such as beginning formal education (usually at about age 6 in most cultures) and retirement (which takes place during the fifties and sixties in most cultures).

normative history-graded influences Influences that are common to people of a particular generation because of historical circumstances.

Normative history-graded influences are common to people of a particular generation because of historical circumstances (Goodey, 2021). For example, in their youth, American baby boomers shared experiences that included the Cuban missile crisis, the assassination of John F. Kennedy, and the Beatles invasion. Other examples of normative history-graded influences include economic, political, and social upheavals such as the Great Depression of the 1930s, World War II during the 1940s, the civil rights and women's rights movements of the 1960s and 1970s, the terrorist attacks of 9/11/2001, as well as the integration of computers, smartphones, the Internet, and social media into everyday life in recent decades (Jarman & others, 2021; Pittinsky, 2020). Long-term changes in the genetic and cultural makeup of a population (due to immigration or changes in fertility rates) are also part of normative historical change.

nonnormative life events Unusual occurrences that have a major impact on an individual's life.

Nonnormative life events are unusual occurrences that have a major impact on an individual's life. These events do not happen to all people, and when they do occur they can influence people in different ways (Masten, 2021a, b; Masten, Motti-Stefanidi, & Rahl, 2020). Examples include experiencing the death of a parent when one is still a child, becoming pregnant in early adolescence, surviving a fire that destroys one's home, winning the lottery, or getting an unexpected career opportunity.

Nonnormative life events, such as Hurricane Maria in Puerto Rico in 2017, are unusual circumstances that can have a major influence on a person's development.
Mario Tama/Staff/Getty Images

Development Involves Growth, Maintenance, and Regulation of Loss Baltes and his colleagues (2006) assert that achieving mastery of life often involves conflicts and competition among three goals of human development: growth, maintenance, and regulation of loss. As individuals age into middle and late adulthood, the maintenance and regulation of loss in their capacities shift their attention away from growth. Thus, a 75-year-old man might aim not to improve his memory or his golf swing but to maintain his independence and merely to continue playing golf.

Development Is a Co-construction of Biology, Culture, and the Individual Development is a co-construction of biological, cultural, and individual factors working together (Baltes, Reuter-Lorenz, & Rosler, 2012). For example, the brain shapes culture, but it is also shaped by culture and the experiences that individuals have or pursue (Han & Maketa, 2021;

Gustavo Medrano, Clinical Psychologist

Gustavo Medrano specializes in helping children, adolescents, and adults of all ages improve their lives when they have problems involving depression, anxiety, emotion regulation, chronic health conditions, and life transitions. He works individually with clients and provides therapy for couples and families. As a native Spanish speaker, he also provides bicultural and bilingual therapy for clients.

Dr. Medrano is a faculty member at the Family Institute at Northwestern University. He obtained his undergraduate degree in psychology at Northwestern and then became a teacher for Teach for America, which involves a minimum of two years spent teaching in a high-poverty area. He received his master's and doctoral degrees in clinical psychology at the University of Wisconsin—Milwaukee. As a faculty member at Northwestern, in addition to doing clinical therapy with clients, he also conducts research with a focus on how family experiences, especially parenting, influence children's and adolescents' coping and pain.

Gustavo Medrano, clinical psychologist, who does therapy with children, adolescents, and adults, especially using his bilingual background and skills to work with Latinx clients.

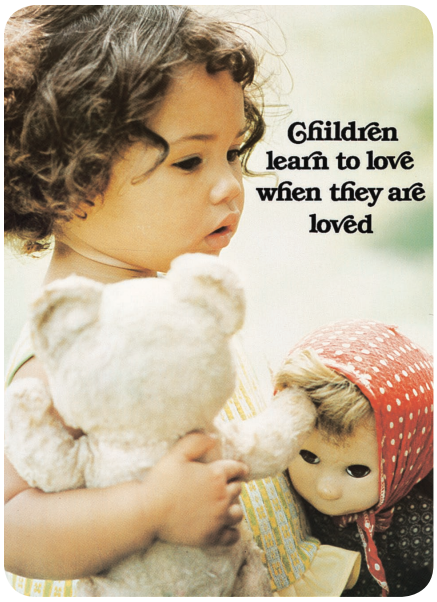
Leoni De Sousa & others, 2021). In terms of individual factors, we can go beyond what our genetic inheritance and environment have given us. We can author a unique developmental path by actively choosing from the environment the things that optimize our lives (Rathunde & Csikszentmihalyi, 2006).

SOME CONTEMPORARY CONCERNS

Search any news source and you might see headlines like these: "Screen Time Linked to Children's Obesity," "Political Leanings May Be Written in the Genes," "Gender Gap Widens," "FDA Warns About Side Effects of ADHD Drug," "Religious Group Protests Transgender Bathrooms," "COVID-19 Rates Higher Among African Americans," "Test May Predict Alzheimer Disease." Researchers using the life-span perspective are examining these and many other topics of contemporary concern. The roles that health and well-being, parenting, education, and sociocultural contexts play in life-span development, as well as how social policy is related to these issues, are a particular focus of *A Topical Approach to Life-Span Development*.

Health and Well-Being Health professionals today recognize the power of lifestyles and psychological states in health and well-being (Brannon, Updegraff, & Feist, 2021; Taylor, 2021). Does a pregnant woman endanger her fetus if she drinks a few beers per week? How does a poor diet affect a child's ability to learn? Are children getting less exercise today than in the past? What roles do parents and peers play in whether adolescents abuse drugs? What health-enhancing and health-compromising behaviors do college students engage in? What factors are causing the obesity epidemic in the United States and around the world? How can older adults cope with declining health? We will discuss many questions like these regarding health and well-being (Powers & Howley, 2021; Sparling & Redican, 2021). In every chapter, issues of health and well-being are integrated into our discussion.

Clinical psychologists are among the health professionals who help people improve their well-being. Read about one clinical psychologist who helps adolescents and adults improve their developmental outcomes in the *Connecting with Careers* profile.



Robert Maust/Photo Agora

Parenting and Education Can two gay men raise a healthy family? Are children harmed if both parents work outside the home? Are U.S. schools failing to teach children how to read and write and calculate adequately? We hear many questions like these related to pressures on the contemporary family and the problems of U.S. schools (Zibulsky & Schwartz, 2021). In other chapters, we analyze child care, the effects of divorce, parenting styles, intergenerational relationships, early childhood education, relationships between childhood poverty and education, stress and well-being of immigrant children, dual-language learning, children with disabilities, new educational efforts to improve lifelong learning, and many other issues related to parenting and education (De Haene & Rousseau, 2020; McKerracher, 2021).

Sociocultural Contexts and Diversity Health, parenting, and education–like development itself–are shaped by their sociocultural context (Landis & Bhawuk, 2021). In analyzing this context, four concepts are especially useful: culture, ethnicity, socioeconomic status, and gender.

Culture encompasses the behavior patterns, beliefs, and all other products of a particular group of people that are passed on from generation to generation. Culture results from the interaction of people over many years (Kulich & others, 2021). A cultural group can be as large as the United States or as small as an isolated Appalachian town. Whatever its size, the group's culture influences the behavior of its members. **Cross-cultural studies** compare aspects of two or more cultures. The comparison provides information about the degree to which development is similar, or universal, across cultures, or instead is culture-specific (Bhawuk & Landis, 2021; Mahon & Cushner, 2021). For example, in a recent study of 26 countries, individuals in Chile had the highest life satisfaction, those in Bulgaria and Spain the lowest (Jang & others, 2017).

Ethnicity (the word *ethnic* comes from the Greek word for "nation") is rooted in cultural heritage, nationality, race, religion, and language. African Americans, Latinxs, Asian Americans, Native Americans, European Americans, and Arab Americans are examples of broad ethnic groups in the United States. Diversity exists within each ethnic group (Gollnick & Chinn, 2021). A special concern is the discrimination and prejudice experienced by ethnic minority children and youth (Clauss-Ehlers, Roysircar, & Hunter, 2021). Recent research by Adriana Umaña-Taylor and her colleagues (Sladek, Umaña-Taylor, & others, 2020; Umaña-Taylor & Hill, 2020) indicates that pride in one's ethnic identity group and exploration of ethnic identity development have positive outcomes.

The sociocultural context of the United States has become increasingly diverse in recent years. Its population includes a greater variety of cultures and ethnic groups than ever before. Relatively high rates of minority immigration have contributed significantly to the growth in the proportion of ethnic minorities in the U.S. population (Schwartz & others, 2020). In 2017, 50.5 percent of children 17 years and younger were non-Latinx White; by 2050, this figure is projected to decrease to 38.8 percent (ChildStats.gov, 2018). In 2017 in the United States, 25.2 percent of children were Latinx, but in 2050 that figure is projected to increase to 31.9 percent. Asian Americans are expected to be the fastest-growing ethnic group of children percentage-wise: In 2017, 5.1 percent were Asian American, and that figure is expected to grow to 7.4 percent in 2050. The percentage of African American children is anticipated to decrease from 2017 to 2050 (13.6 to 13.1 percent). This changing demographic tapestry promises not only the richness that diversity produces but also difficult challenges in extending the American dream to all individuals (Banks, 2020). In 2020, the deadly effects of racial discrimination took center stage in the United States as not only African Americans but members of other groups protested the killing of African Americans such as George Floyd by White police officers.

Socioeconomic status (SES) refers to a person's position within society based on occupational, educational, and economic characteristics. Socioeconomic status implies certain inequalities. Differences in the ability to control resources and to participate in society's rewards produce unequal opportunities (Mayo & Wadsworth, 2020). For example, a recent research review of 3- to 19-year-old U.S. children and adolescents concluded that growing up in low-SES settings is associated with higher levels of psychopathology (Peverill & others, 2021).

Gender refers to the characteristics of people as males and females. Few aspects of our development are more central to our identity and social relationships than gender (Brown, Biefeld, & Tam, 2021; Cheung & Halpern, 2021).

Recently, considerable attention has focused on a category of gender classification, *transgender,* a broad term that refers to individuals who adopt a gender identity that differs from the one assigned to them at birth (Ellis, Riggs, & Peel, 2020; Spizzirri & others, 2021). For example, individuals may have a female body but identify more strongly with being masculine than feminine, or have a male body but identify more strongly with being feminine

Doly Akter, pictured here at age 17, grew up in a slum in Dhaka, Bangladesh, where sewers overflowed, garbage rotted in the streets, and children were undernourished. Nearly two-thirds of young women in Bangladesh marry before they are 18. Doly organized a club supported by UNICEF in which girls go door-to door monitoring the hygiene habits of households in their neighborhood, leading to improved hygiene and health in the families. Also, her group has stopped several child marriages by meeting with parents and convincing them that it is not in their daughter's best interests. The girls in the club emphasize the importance of staying in school and how this will improve their daughters' future. Doly says that the girls in her UNICEF group are far more aware of their rights than their mothers ever were (UNICEF, 2007).
Naser Siddique/UNICEF Bangladesh

than masculine. A transgender identity of being born male but identifying with being a girl/woman is much more common than the reverse (Zucker, Lawrence, & Kreukels, 2016). We will have much more to say about gender and transgender later in the text.

In this section, you have read about important aspects of individuals such as their cultural and socioeconomic backgrounds, ethnicity, and gender. As people go through the human life-span, these categories intersect and can create systems of power and privilege as well as oppression and discrimination. For example, higher-socioeconomic-status non-Latinx White boys/men have experienced considerably greater privilege and less discrimination than African American girls/women. At various points in this text, we will further explore these category connections.

Social Policy

Social policy is a government's course of action designed to promote the welfare of its citizens. Values, economics, and politics all shape a nation's social policy (Font & others, 2020). Out of concern that policy makers are doing too little to protect the well-being of children and older adults, life-span researchers are increasingly undertaking studies that they hope will lead to the enactment of effective social policy (Vescio & Kosakowska-Berezecka, 2021).

Statistics such as infant mortality rates, mortality among children under age 5, and the percentage of children who are malnourished or living in poverty provide benchmarks for evaluating how well children are doing in a particular society (UNICEF, 2021). For many years, Marian Wright Edelman, an American activist for children's rights, has pointed out that

Marian Wright Edelman, president of the Children's Defense Fund (shown here advocating for health care), has been a tireless advocate of children's rights and instrumental in calling attention to the needs of children. *What are some of these needs?*

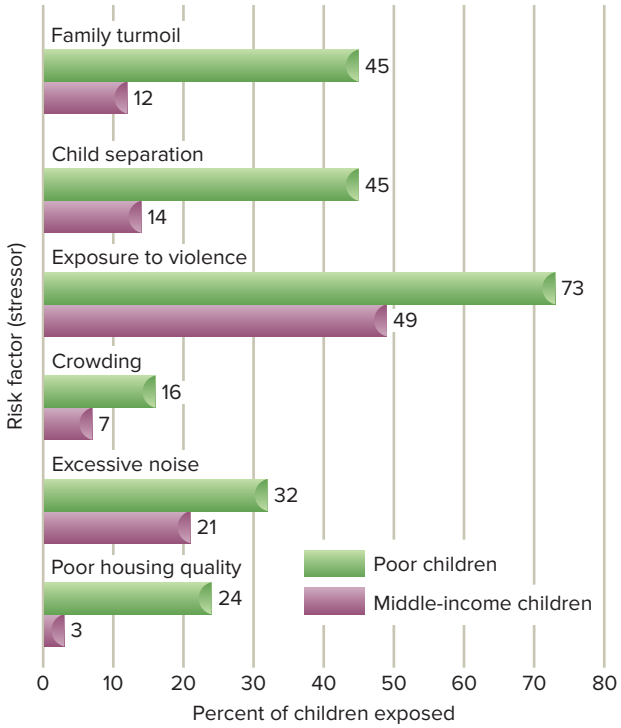

FIGURE 3

EXPOSURE TO SIX STRESSORS AMONG POOR AND MIDDLE-INCOME CHILDREN. One study analyzed the exposure to six stressors among poor children and middle-income children (Evans & English, 2002). Poor children were much more likely to face each of these stressors.

indicators like these place the United States at or near the lowest rank among industrialized nations in the treatment of children.

Children who grow up in poverty represent a special concern. In 2019, 14.4 percent of U.S. children under 18 years of age were living in families with incomes below the poverty line, a decrease from 2018 (16.2 percent) as well as a decrease from a peak of 23 percent in 1993 (Semega & others, 2020). In 2019, African American (26.4 percent, down from 30.1 percent in 2018) and Latinx (20.9 percent, down from 23.7 percent in 2018) families with children had especially high rates of poverty (Semega & others, 2020). In 2019, 7.3 percent of Asian American children (down from 11.3 percent in 2018) and 8.3 percent of non-Latinx White U.S. children (down from 8.9 percent) were living below the poverty line.

As indicated in Figure 3, one study found that a higher percentage of U.S. children in poor families than in middle-income families were exposed to family turmoil, separation from a parent, violence, crowding, excessive noise, and poor housing (Evans & English, 2002). Another study revealed that the more years children spent living in poverty, the higher were their physiological indices of stress (Evans & Kim, 2007).

The U.S. figure of 14.4 percent of children living in poverty is much higher than child poverty rates in other industrialized nations. For example, Canada has a child poverty rate of 9 percent and Sweden has a rate of 2 percent.

Edelman says that parenting and nurturing the next generation of children are our society's most important functions and that we need to take them more seriously than we have in the past. To read about efforts to improve the lives of children through social policies, see *Connecting Development to Life*.

Some children triumph over poverty or other adversities. They show resilience. Are there certain characteristics that make children resilient? Ann Masten and her colleagues (2009, 2015, 2019, 2021a, b; Masten, Motti-Stefanidi, & Rahl, 2020; Masten & Palmer, 2019; Masten & others, 2021) conclude that individual factors, especially good intellectual functioning, and social contexts, especially positive parenting, are key attributes of children who show resilience in the face of adversity. Figure 4 shows the individual factors and social contexts that tend to characterize resilient children.

At the other end of the life span, efforts to promote the well-being of older adults also create policy issues (Sanchez, 2021). Key concerns are controlling health-care costs and ensuring that older adults have access to adequate health care (deJong-Monroe, 2021). These concerns about the well-being of older adults are heightened by two facts. First, the number of older adults in the United States is growing dramatically, as Figure 5 shows. Second, many of these older Americans are likely to need society's help (Madea & Doberentz, 2021). Compared with earlier decades, U.S. adults today are less likely to be married, more likely to be childless, and more likely to live alone (Machielse, 2015). As the older population continues to expand, an increasing number of older adults will be without either a spouse or children—traditionally the main sources of support for older adults. These individuals will need social relationships, networks, and supports (Hay, Sageman, & Allan, 2021).

Source	Characteristic
Individual	Good intellectual functioning Appealing, sociable, easygoing disposition Self-confidence, high self-esteem Talents Faith
Family	Close relationship to caring parent figure Authoritative parenting: warmth, structure, high expectations Socioeconomic advantages Connections to extended supportive family networks
Extrafamilial Context	Bonds to caring adults outside the family Connections to positive organizations Attending effective schools

FIGURE 4

CHARACTERISTICS OF RESILIENT CHILDREN: INDIVIDUAL FACTORS AND SOCIAL CONTEXTS.

Technology A final discussion in our exploration of contemporary topics is the recent dramatic, almost overwhelming increase in the use of technology at all points in human development (Maloy & others, 2021). From the introduction of television in the mid '50s, to the replacement of typewriters with computers that can do far more than just print words, and later to the remarkable invention of the Internet and the proliferation of smartphones, followed by the pervasiveness of social media and the development of robots that can do some jobs better than humans can, our way of life has been changed permanently by technological advances.

We will explore many technology topics in this edition. In the "Information Processing" chapter, you will read about the emerging field of

connecting development to life

Improving Family Policy

In the United States, the national government, state governments, and city governments all have the capacity to improve the well-being of children (Worrell, Dixon, & Hughes, 2020). When families neglect or seriously endanger a child's well-being, governments often step in to help. At the national and state levels, policy makers have debated for decades whether helping poor parents will benefit their children. Researchers are providing some answers by examining the effects of specific policies (Andrews & others, 2020).

Increasing interest has been directed toward developing two-generation educational interventions to improve the academic success of children living in poverty (Chase-Lansdale & others, 2019). For example, a recent large-scale effort to help children escape from poverty is the Ascend two-generation educational intervention being conducted by the Aspen Institute (Ascend, 2021; Aspen Institute, 2019). The intervention emphasizes education (increasing postsecondary education for mothers and improving the quality of their children's early childhood education), economic support (housing, transportation, financial education, health insurance, and food assistance), and social capital (peer support, including friends and neighbors; participation in community and faith-based organizations; school and work contacts). In a recent report, the Ascend program emphasized the importance of parents' education, economic stability, and overall health for their children's well-being (Ascend, 2021; Aspen Institute, 2019).

This mother and her daughter are participating in the Ascend program. *What are the characteristics of the Ascend program?*
Studio 1One/Shutterstock

Developmental psychologists and other researchers have examined the effects of many other government policies. They are seeking ways to help families living in poverty improve their well-being, and they have offered many suggestions for improving government policies (Crosby, 2021; Teja & Worrell, 2020).

How does the life-span perspective support this and other research on the role government should play in improving the well-being of children?

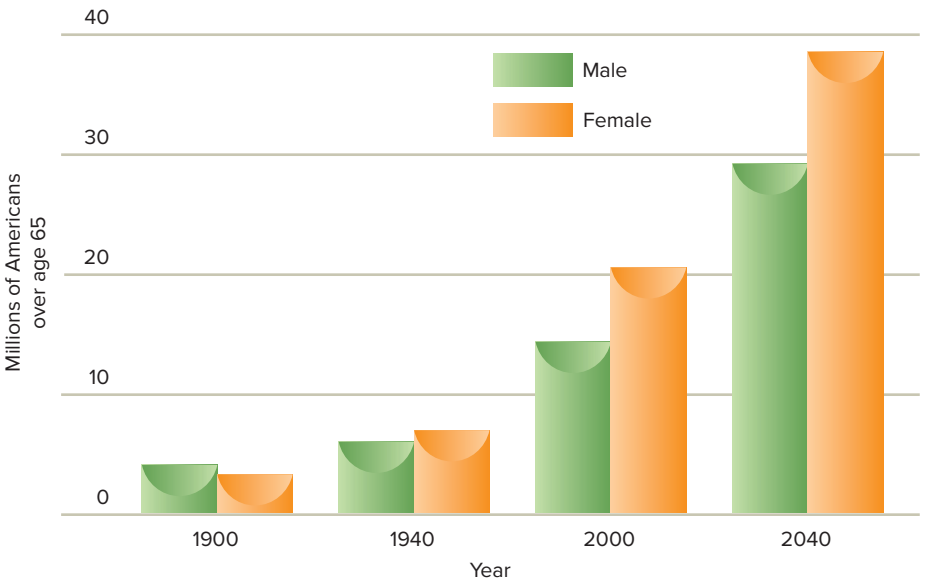

FIGURE **5**

THE AGING OF AMERICA. The number of Americans over 65 has grown dramatically since 1900 and is projected to continue increasing until 2040. A significant increase will also occur in the number of individuals in the 85-and-over age group.

developmental robotics and you will ponder the influence of technology on generations such as the millennials. Other topics we will examine include whether babies should watch television and videos, with special attention to potential effects of audiovisual media on language development; indications that too much screen time reduces children's engagement in physical activities and increases their risk for obesity and cardiovascular disease; the effects on learning when many adolescents spend more time using various media than they do in school; the question of whether multitasking with various electronic devices while doing homework is harmful or beneficial; as well as the degree to which older adults are adapting to the extensive role of technology in their lives, especially since they grew up without so much technology.

Review *Connect* Reflect

LG1 Discuss the distinctive features of a life-span perspective on development.

Review

- What is meant by the concept of development? Why is the study of life-span development important?
- What are eight main characteristics of the life-span perspective? What are three sources of contextual influences on development?

2 The Nature of Development

LG2 Identify the most important processes, periods, and issues in development.

Biological, Cognitive, and Socioemotional Processes | Periods of Development | The Significance of Age | Developmental Issues

In this section, we explore what is meant by developmental processes and periods, as well as variations in the way age is conceptualized. We examine key developmental concepts, explore how they describe development, and discuss strategies we can use to evaluate them.

A chronicle of the events in any person's life can quickly become a confusing and tedious array of details. Two concepts help provide a framework for describing and understanding an individual's development: developmental processes and periods of development.

BIOLOGICAL, COGNITIVE, AND SOCIOEMOTIONAL PROCESSES

At the beginning of this chapter, we defined development as the pattern of change that begins at conception and continues throughout the life span. The pattern is complex because it is the product of biological, cognitive, and socioemotional processes.

biological processes Processes that produce changes in an individual's physical nature.

cognitive processes Processes that involve changes in an individual's thought, intelligence, and language.

Biological Processes

Biological processes produce changes in an individual's physical nature. Genes inherited from parents, the development of the brain, height and weight gains, changes in motor skills, nutrition, exercise, the hormonal changes of puberty, and cardiovascular decline are all examples of biological processes that affect development.

Cognitive Processes

Cognitive processes refer to changes in the individual's thought process, intelligence, and language. Watching a colorful mobile swinging above the crib, putting together a two-word sentence, memorizing a poem, imagining what it would be like to be a movie star, and solving a crossword puzzle all involve cognitive processes.

Socioemotional Processes **Socioemotional processes** involve changes in the individual's relationships with other people, changes in emotions, and changes in personality. An infant's smile in response to a parent's touch, a toddler's aggressive attack on a playmate, a school-age child's development of assertiveness, an adolescent's joy at the senior prom, and the affection of an elderly couple all reflect the influence of socioemotional processes on development.

socioemotional processes Processes that involve changes in an individual's relationships with other people, emotions, and personality.

Connecting Biological, Cognitive, and Socioemotional Processes Biological, cognitive, and socioemotional processes are inextricably intertwined (Diamond, 2013). Consider a baby smiling in response to a parent's touch. This response depends on biological processes (the physical nature of touch and responsiveness to it), cognitive processes (the ability to understand intentional acts), and socioemotional processes (the act of smiling often reflects a positive emotional feeling and helps to connect us in positive ways with other human beings). Nowhere is the connection across biological, cognitive, and socioemotional processes more obvious than in two rapidly emerging fields:

- *Developmental cognitive neuroscience,* which explores links between development, cognitive processes, and the brain (Bell & Broomell, 2021)
- *Developmental social neuroscience,* which examines connections between socioemotional processes, development, and the brain (Kirmayer, Worthman, & Kitayama, 2021)

In many instances, biological, cognitive, and socioemotional processes are bidirectional. For example, biological processes can influence cognitive processes and vice versa. Thus, although usually we study the different processes of development (biological, cognitive, and socioemotional) in separate locations, keep in mind that we are talking about the development of an integrated individual with a mind and body that are interdependent.

PERIODS OF DEVELOPMENT

What are the most commonly agreed upon age periods of development? Might the age ranges and characteristics of the age periods have recently changed?

Eight-Period Sequence of Developmental Periods The interplay of biological, cognitive, and socioemotional processes produces the periods of the human life span (see Figure 6). *A developmental period* refers to a time frame in a person's life that is characterized by certain features. For the purposes of organization and understanding, we commonly describe development in terms of these periods. The most widely used classification of developmental periods involves the eight-period sequence shown in Figure 7. Approximate age ranges are listed for the periods to provide a general idea of when each period begins and ends.

The prenatal period is the time from conception to birth. It involves tremendous growth—from a single cell to an organism complete with brain and behavioral capabilities—and takes place within approximately a nine-month period.

Infancy is the developmental period from birth to 18 or 24 months. Infancy is a time of extreme dependence upon adults. During this period, many psychological activities—language, symbolic thought, sensorimotor coordination, and social learning, for example—are just beginning.

Early childhood is the developmental period from the end of infancy to age 5 or 6. This period is sometimes called the "preschool years." During this time, young children learn to become more self-sufficient and to care for themselves, develop school readiness skills (following instructions, identifying letters), and spend many hours in play with peers. First grade typically marks the end of early childhood.

Middle and late childhood is the developmental period from about 6 to 11 years of age, approximately corresponding to the elementary school years. During this period, the fundamental skills of reading, writing, and arithmetic are mastered. The child is formally exposed to the larger world and its culture. Achievement becomes a more central theme of the child's world, and self-control increases.

Adolescence is the developmental period of transition from childhood to early adulthood, entered at approximately 10 to 12 years of age and ending at 18 to 21 years of age. Adolescence begins with rapid physical changes—dramatic gains in height and weight, changes in body contour, and the development of sexual characteristics such as enlargement of the breasts, growth of pubic and facial hair, and deepening of the

voice. At this point in development, the pursuit of independence and an identity are prominent. Thought is more logical, abstract, and idealistic. More time is spent outside the family.

Early adulthood is the developmental period that begins in the twenties and lasts through the thirties. It is a time of establishing personal and economic independence, pursuing career development, and, for many, selecting a mate, learning to live with someone in an intimate way, starting a family, and rearing children.

Middle adulthood is the developmental period from approximately 40 years of age to about 60. It is a time of expanding personal and social involvement and responsibility; of assisting the next generation in becoming competent, mature individuals; and of reaching and maintaining satisfaction in a career.

Late adulthood is the developmental period that begins during the sixties or seventies and lasts until death. It is a time of life review, retirement from paid employment, and adjustment to new social roles involving decreasing strength and health. Late adulthood is the longest period of development, and—as noted earlier—the number of people in this age group has been increasing dramatically. As a result, life-span developmentalists have been paying more attention to differences within late adulthood. Paul Baltes and Jacqui Smith (2003) argue that a major change takes place in older adults' lives as they become the "oldest old," on average at about 85 years of age. For example, the "young old" (classified as 65 through 84 in this analysis) have substantial potential for physical and cognitive fitness, retain much of their cognitive capacity, and can develop strategies to cope with the gains and losses of aging. In contrast, the oldest old (85 and older) show considerable loss in cognitive skills, experience an increase in chronic stress, and become more frail (Baltes & Smith, 2003). Nonetheless, as we see in other chapters, considerable variation exists in the degree to which the oldest old retain their capabilities (Cho & others, 2020). As described in the *Connecting with Research* interlude, situational contexts, including time of day, play an important role in how well older adults perform in cognitive and physical activities.

Are Age Ranges for Adult Periods of Development Changing?

When we described periods of development, we also outlined age ranges for the periods. Might the age ranges and characteristics of these periods be changing?

connecting with research

Is There a Best Time of Day to Conduct Research?

Courtesy Lynn Hasher

Lynn Hasher

Key Points:

- memory
- older adults compared to younger adults
- time of day assessed

Might certain testing conditions exaggerate the severity of age-related declines in older adults' performance? Optimum testing conditions are not the same for young adults as they are for older adults (Helmuth, 2003). Most researchers conduct their studies in the afternoon, a convenient time for researchers and undergraduate participants. Traditional-aged college students in their late teens and early twenties are often more alert and function optimally in the afternoon, but about 75 percent of older adults are "morning people" who perform at their best early in the day (Helmuth, 2003).

Lynn Hasher and her colleagues (2001) tested the memory of college students 18 to 22 years of age and community volunteers 58 to 78 years of age in the late afternoon (about 4 to 5 p.m.) and in the morning (about 8 to 9 a.m.). Regardless of the time of day, the younger college students performed better than the older adults on the memory tests, which involved recognizing sentences from a story and memorizing a list of words. However, when the participants took the memory tests in the morning rather than in the late afternoon, the age difference in performance decreased considerably (see Figure 8).

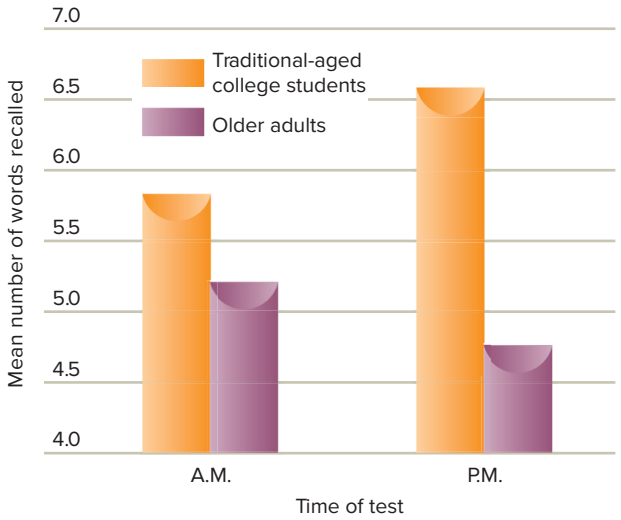

FIGURE **8**

MEMORY, AGE, AND TIME OF DAY TESTED (A.M. or P.M.) In one study, traditional-aged college students performed better than older adults in both the morning and the afternoon. Note, however, that the memory of the older adults was better when they were tested in the morning than in the afternoon, whereas the memory of the traditional-aged college students was not as good in the morning as it was in the afternoon (Hasher & others, 2001).

Emerging Adulthood and Early Adulthood Recently, considerable interest has been directed toward the period of transition from adolescence to adulthood, now referred to as **emerging adulthood,** which lasts from approximately 18 to 25 years of age. Experimentation and exploration characterize the emerging adult (Arnett, 2006, 2016). At this point in their development, many individuals are still exploring which career path they want to follow, what they want their identity to be, and which lifestyle they want to adopt (for example, single, cohabiting, or married) (Becht & others, 2021; Henneberger, Witzen, & Preston, 2021).

Jeffrey Arnett (2006) described five key features that characterize emerging adulthood:

- *Identity exploration,* especially in love and work. Emerging adulthood is the time during which key changes in identity take place for many individuals.
- *Instability*. Residential changes peak during emerging adulthood, a time during which there also is often instability in love, work, and education.
- *Self-focused*. According to Arnett (2006, p. 10), emerging adults "are self-focused in the sense that they have little in the way of social obligations, little in the way of duties and commitments to others, which leaves them with a great deal of autonomy in running their own lives."
- *Feeling in-between*. Many emerging adults don't consider themselves adolescents or full-fledged adults.
- *The age of possibilities, a time when individuals have an opportunity to transform their lives.* Arnett (2006) describes two ways in which emerging adulthood is the age of possibilities: (1) many emerging adults are optimistic about their future; and (2) for emerging adults who have experienced difficult times while growing up, emerging adulthood presents an opportunity to direct their lives in a more positive way.

emerging adulthood The developmental time frame occurring from approximately 18 to 25 years of age; this transitional period between adolescence and adulthood is characterized by experimentation and exploration.

What do you think the age range for emerging adults should be?
Andresr/Getty Images

Recent research indicates that these five aspects characterize not only individuals in the United States as they make the transition from adolescence to early adulthood, but also their counterparts in European countries and Australia (Arnett, 2015; Sirsch & others, 2009). Although emerging adulthood does not characterize a specific period of development in all cultures, it does appear to occur in those where assuming adult roles and responsibilities is postponed (Kins & Beyers, 2010).

Increasingly, instead of describing emerging adulthood as occurring from 18 to 25 years of age, the age range has been expanded to 18 to 29 (Arnett, 2015). However, in a recent study of individuals 18 to 60, the five characteristics of emerging adulthood mentioned above (identity exploration, self-focus, feeling in-between, instability, and possibilities/optimism) were more likely to be endorsed by 18- to 25-year-olds than by older individuals (Arnett & Mitra, 2020).

In earlier generations, by their mid-twenties at the latest, individuals were expected to have finished college, obtained a full-time job, and established their own household, most often with a spouse and a child. However, individuals are now taking much longer to reach these developmental milestones, many of which they are not experiencing until their late twenties or even thirties (Vespa, 2017). The best-paying jobs today increasingly require the ability to use information and technology. Individuals are spending more time preparing for careers than ever before, and as a result they are postponing marriage and parenting (Arnett, Robinson, & Lachman, 2020). It is not surprising that their parents recall having had a much earlier timetable of reaching these developmental milestones.

Thus, today there are proposals for *early adulthood* (or a new term, *established adulthood*) to range from approximately 30 to 45 years of age (Mehta & others, 2020). The key factor defining this period would be the delay of more stable work and family patterns (getting married and having children, for example) until this later time frame.

Age Range for Middle Adulthood Many of today's 50-year-olds are in better shape, more alert, and more productive than their 40-year-old counterparts from a generation or two earlier. As more people lead healthier lifestyles and medical discoveries help to slow down the aging process, the boundaries of middle age are being pushed upward. It seems that middle age is starting later and lasting longer for increasing numbers of active, healthy, and productive people. A current saying is "60 is the new 40," implying that many 60-year-olds today are living a life that is as active, productive, and healthy as earlier generations did in their forties.

Questions such as "To which age group do you belong?" and "How old do you feel?" reflect the concept of *age identity*. A consistent finding is that as adults become older their age identity is younger than their chronological age (Westerhof, 2009). For example, a recent study found that middle-aged adults 44 to 64 years of age reported feeling younger than they actually were and wanting to be younger than their chronological age (Shinan-Altman & Werner, 2019). In this study, the perceived beginning of old age was 69 years. And a British survey of people over 50 years of age revealed that they perceived middle age to begin at 53 (Beneden Health, 2013). Also, some individuals perceive the upper boundary of midlife as the age when they make the transition from work to retirement.

When Swiss psychiatrist Carl Jung studied midlife transitions early in the twentieth century, he referred to midlife as "the afternoon of life" (Jung, 1933). Midlife serves as an important preparation for late adulthood, "the evening of life" (Lachman, 2004, p. 306). But "midlife" came much earlier in Jung's time. In 1900 the average life expectancy was only 47 years of age; only 3 percent of the population lived past 65. Today, as you read earlier in the chapter, the average life expectancy is 79, and 12 percent of the U.S. population is older than 65 (Arias & Xu, 2019). As a much greater percentage of the population lives to older ages, the midpoint of life and what constitutes middle age or middle adulthood are getting harder to pin down. Statistically, the middle of life today is about 39.5 years of age, but most 39-year-olds don't want to be called "middle-aged." What we think of as middle age comes later—anywhere from 45 to 65 years of age. And as more people live longer, the upper boundary of middle age will likely be nudged higher still.

Changing Late Adulthood As the boundaries of middle age are pushed upward, the period of late adulthood begins later as well (Arnett, Robinson, & Lachman, 2020). As we

saw earlier in the chapter, the average life expectancy at birth is currently the highest it has ever been (79 years in the United States) (Arias & Xu, 2019). Also, life expectancy at age 65 is the highest it has ever been—20 or more years in most developed countries and approaching 20 years even in developing countries such as Mexico (OECD, 2019). Coupled with declining rates of childbearing, the trend toward longer life spans mean that older adults are a larger percentage of the populations of developed countries than in the past (Kitayama, Berg, & Chopik, 2020). And as you read earlier about the young old (65 to 84) and the oldest old (85 and older), the young old are more physically and cognitively fit than their counterparts in prior decades as a result of lifestyle changes and medical improvements (Freund, 2020; Staudinger, 2020). For too long, late adulthood was perceived as a period of physical, cognitive, and socioemotional decline beginning at about 65 years of age. Currently, an increasing number of older adults are adapting in healthy ways to their aging and enjoying a higher quality of life. In later chapters, these changing aspects of adult life will be discussed further.

THE SIGNIFICANCE OF AGE

In the earlier description of developmental periods, an approximate age range was linked with each period. As you just read, the chronological boundaries of these age periods may be changing, as well as characteristics of the age periods. There are also variations in the capabilities of individuals who are the same age, and we have seen how changes with age can be exaggerated. How important is age when we try to understand an individual?

Age and Happiness Is one age in life better than another? An increasing number of studies indicate that at least in the United States adults are happier as they age. For example, a study of more than 300,000 U.S. adults revealed that psychological well-being increased after the age of 50 years (Stone & others, 2010). In a recent study of individuals from 22 to 93 years of age, older adults reported having more positive emotional experiences than younger adults did (English & Carstensen, 2014).

Consider also a U.S. study of approximately 28,000 individuals from age 18 to 88 that revealed happiness increased with age (Yang, 2008). For example, about 33 percent were very happy at 88 years of age, compared with only about 24 percent in their late teens and early twenties. Why might older people report being happier and more satisfied with their lives than younger people? Despite the increase in physical problems and losses older adults experience, they are more content with their lives, have better relationships with the people who matter to them, are less pressured to achieve, have more time for leisurely pursuits, and have many years of experience that may help them use their accrued wisdom to adapt better to their circumstances than younger adults do (Paul, 2019). Also in this study, baby boomers (those born between 1946 and 1964) reported being less happy than individuals born earlier—possibly because they are not lowering their aspirations and idealistic hopes as earlier generations did. Also, in a recent study, individuals' happy life expectancy at age 65 was 25 percent longer than their cognitive impairment life expectancy, and at 85 years their happy life expectancy doubled to 50 percent greater than their cognitive impairment life expectancy (Bardo & Lynch, 2021). Because growing older is a certain outcome of living, it is good to know that we are likely to be happier as older adults than we were during earlier periods of our lives. Further, in a recent study of 18- to 76-year-olds in April 2020, Laura Carstensen and her colleagues (2020) asked participants to report the frequency and intensity of their emotions over the past week, how risky they perceived COVID-19 to be to themselves and others, and how much time and opportunity they thought they had remaining in their lives. Older adults reported more frequent positive emotions and less intense negative emotions than younger adults despite being more aware of the risks COVID-19 had for them. The effect remained even though older adults estimated that they had less time left in life.

However, not all research indicates that increased life satisfaction accompanies increased age (Steptoe, Deaton, & Stone, 2015). Some studies indicate that the lowest levels of life satisfaction occur in middle age, especially from 45 to 54 years of age (OECD, 2014). Other studies have found that life satisfaction varies across some countries. For example, respondents in research studies conducted in the former Soviet Union and Eastern Europe, as well as in South American countries, reported decreased life satisfaction with advancing age (Deaton, 2008). Further, older adults in poor health, such as those with cardiovascular disease, chronic lung disease, and depression, tend to be less satisfied with their lives than their healthier older adult counterparts are (Lamont & others, 2017). A recent study across 150 countries found

Below are five statements that you may agree or disagree with. Using the 1–7 scale below, indicate your agreement with each item by placing the appropriate number on the line preceding that item. Please be open and honest in your responding.

Scale
7 Strongly agree
6 Agree
5 Slightly agree
4 Neither agree nor disagree
3 Slightly disagree
2 Disagree
1 Strongly disagree

Response	Statement
_____	In most ways my life is close to my ideal.
_____	The conditions of my life are excellent.
_____	I am satisfied with my life.
_____	So far I have gotten the important things I want in life.
_____	If I could live my life over, I would change almost nothing.
_____	Total score

Scoring	
31–35	Extremely satisfied

that health was a better predictor of life satisfaction in individuals 58 years and older than in younger age groups (Joshanloo & Joyanovic, 2021).

Now that you have read about age variations in life satisfaction, think about how satisfied you are with your life. To help you answer this question, complete the items in Figure 9, which presents the most widely used measure in research on life satisfaction (Diener, 2021).

Conceptions of Age

Chronological age—the number of years that have elapsed since birth—is not the only way to measure age. Age has been conceptualized not just as chronological age but also as biological age, psychological age, and social age (Hoyer & Roodin, 2009).

Biological age is a person's age in terms of biological health. Determining biological age involves knowing the functional capacities of a person's vital organs. One person's vital capacities may be better or worse than those of others of comparable age (Kim & others, 2021). A study of 17-year survival rates in Korean adults 20 to 93 years of age found that mortality rates were higher for individuals whose biological age was greater than their chronological age (Yoo & others, 2017). Also, a recent study revealed that biological age was a good predictor of whether an adult would have a stroke recurrence (Soriano-Tarraga & others, 2021). In sum, the younger a person's biological age, the longer the person is expected to live, regardless of chronological age.

Psychological age reflects an individual's adaptive capacities compared with those of other individuals of the same chronological age. Thus, older adults who continue to learn, are flexible, cope effectively with stress, think clearly, and are conscientious are engaging in more adaptive behaviors than their chronological age-mates who don't possess these characteristics (Matthews, 2021). Reflecting the importance of psychological age, a longitudinal study of more than 1,200 individuals across seven decades revealed that the personality trait of conscientiousness (being organized, careful, and disciplined, for example) predicted lower mortality risk from childhood through late adulthood (Martin, Friedman, & Schwartz, 2007). Another study found that a higher level of conscientiousness was protective of cognitive functioning in older adults (Wilson & others, 2015).

Social age refers to connectedness with others and the social roles individuals adopt. Individuals who have better social relationships with others are happier with their lives and are likely to live longer than those who are lonely (Streeter, Raposo, & Liao, 2020).

(*Left*) Pam McSwain, competing in the high jump in the Senior Olympics in Memphis; (*right*) a sedentary, overweight middle-aged man. *Even though Pam McSwain's chronological age is older, might her biological age be younger than the middle-aged man's?*

(*Left*): Karen Pulfer Focht/The Commercial Appeal/Landov Images; (*Right*): Owaki-Kulla/Getty Images

From a life-span perspective, an overall age profile of an individual involves not just chronological age but also biological age, psychological age, and social age. For example, a 70-year-old man (chronological age) might be in good physical health (biological age), be experiencing memory problems and not coping well with the demands placed on him by his wife's recent hospitalization (psychological age), and have a number of friends with whom he regularly plays golf (social age).

Three Developmental Patterns of Aging K. Warner Schaie (2016) described three different developmental patterns that illustrate how aging can involve individual variations:

- *Normal aging* characterizes most individuals; in this pattern psychological functioning often peaks in early middle age, remains relatively stable until the late fifties to early sixties, and then shows a modest decline through the early eighties. However, marked decline can occur as individuals near death.
- *Pathological aging* characterizes individuals who show greater than average declines as they age through the adult years. For example, they may have mild cognitive impairment in early old age, develop Alzheimer disease later on, or have a chronic disease that impairs their daily functioning.
- *Successful aging* characterizes individuals whose positive physical, cognitive, and socioemotional development is maintained longer, declining later in old age than is the case for most people. For too long, only the declines that occur in late adulthood were highlighted, but recently there has been increased interest in the concept of successful aging (Esteves & others, 2021).

DEVELOPMENTAL ISSUES

Is your own journey through life marked out ahead of time, or can your life experiences change your path? Are the experiences that take place early in your journey more important than later ones? Is your journey more like taking an elevator up a skyscraper with distinct stops along the way, or more like cruising down a river with smoother ebbs and flows? These questions point to three issues about the nature of development: the roles played by nature and nurture, by stability and change, and by continuity and discontinuity.

Nature and Nurture The **nature-nurture issue** involves the extent to which development is influenced by nature and by nurture. Nature refers to an organism's biological inheritance, nurture to its environmental experiences.

According to those who emphasize the role of nature, just as a sunflower grows in an orderly way—unless flattened by an unfriendly environment—so too a human grows in an orderly way. An evolutionary and genetic foundation produces commonalities in growth and development (Mason, Duncan, & Losos, 2021). We walk before we talk, speak one word before two words, grow rapidly in infancy and less so in early childhood, experience a rush of sex hormones in puberty, reach the peak of our physical strength in late adolescence and early adulthood, and then decline physically. Proponents of the developmental influence of nature acknowledge that extreme environments—those that are psychologically barren or hostile—can depress development. However, they believe that basic growth tendencies are genetically programmed into humans (Hoefnagels, 2021).

By contrast, others emphasize the impact of nurture, or environmental experiences, on development (Bembenutty, 2021; Kuo, 2021). Experiences run the gamut from the individual's biological environment (nutrition, medical care, drugs, and physical accidents) to the social environment (family, peers, schools, community, media, and culture).

There has been a dramatic increase in the number of studies that reflect the *epigenetic view,* which states that development reflects an ongoing, bidirectional interchange between genes and the environment. These studies involve specific DNA sequences (Franzago & others, 2020). The epigenetic mechanisms involve the actual molecular modification of the DNA strand as a result of environmental inputs in ways that alter gene functioning (Champagne, 2021). In "Biological Beginnings" we will explore the epigenetic approach in greater depth.

Stability and Change Is the shy child who hides behind the sofa when visitors arrive destined to become a wallflower at college dances, or might the child become a sociable, talkative individual? Is a fun-loving, carefree adolescent bound to have difficulty holding down a 9-to-5 job as an adult? These questions reflect the **stability-change issue,**

Personality
Is personality more stable at some points in adult development than at others? Connect to "The Self, Identity, and Personality."

nature-nurture issue Debate about whether development is primarily influenced by nature or nurture.

stability-change issue Debate as to whether and to what degree we become older renditions of our earlier selves (stability) or whether we develop into someone different from who we were at an earlier point in development (change).

continuity-discontinuity issue Debate that focuses on the extent to which development involves gradual, cumulative change (continuity) or distinct stages (discontinuity).

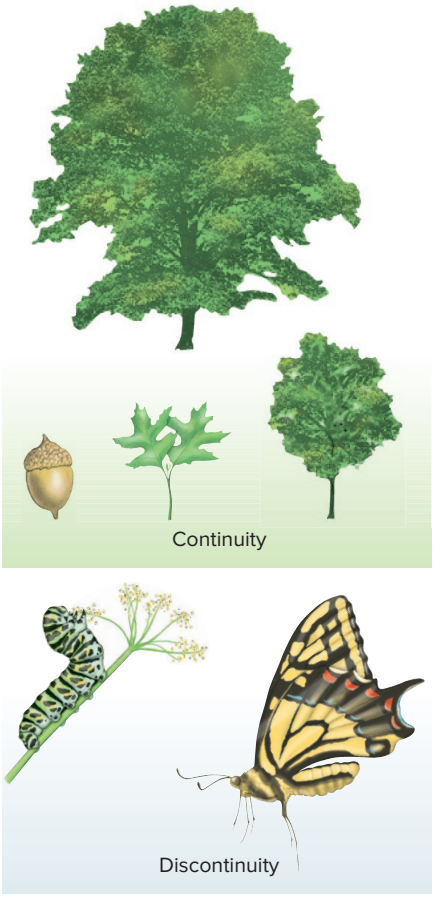

FIGURE **10**

CONTINUITY AND DISCONTINUITY IN DEVELOPMENT. *Is our development like that of a seedling gradually growing into a giant oak tree? Or is it more like that of a caterpillar suddenly becoming a butterfly?*

which involves the degree to which early traits and characteristics persist or change as a person matures.

Many developmentalists who emphasize stability in development argue that stability is the result of heredity and possibly experiences early in life. Developmentalists who emphasize change take the more optimistic view that later experiences can produce change. Recall that in the life-span perspective, plasticity—the potential for change—exists throughout the life span.

The roles of early and later experience are an aspect of the stability-change issue that has long been hotly debated (Dagan & Sagi-Schwartz, 2021). Some argue that unless infants experience warm, nurturant caregiving in the first year or so of life, their development will be less optimal (Waters, Waters, & Waters, 2021). The later-experience advocates see children as malleable throughout development, with sensitive caregiving and positive close relationships playing important roles later in child development, adolescence, and adulthood just as they do in infancy (Mikulincer & Shaver, 2021).

Continuity and Discontinuity

When developmental change occurs, is it gradual or abrupt? Think about your own development for a moment. Did you gradually become the person you are? Or did you experience sudden, distinct changes as you matured? For the most part, developmentalists who emphasize nurture describe development as a gradual, continuous process. Those who emphasize nature often describe development as a series of distinct stages.

The **continuity-discontinuity issue** focuses on the degree to which development involves either gradual, cumulative change (continuity) or distinct stages (discontinuity). In terms of continuity, as the oak grows from seedling to giant tree, it becomes more and more an oak—its development is continuous (see Figure 10). Similarly, a child's first word, though seemingly an abrupt, discontinuous event, is actually the result of weeks and months of growth and practice. Puberty might seem abrupt, but it is a gradual process that occurs over several years.

In terms of discontinuity, as an insect grows from a caterpillar to a chrysalis to a butterfly, it passes through a sequence of stages in which change differs qualitatively rather than quantitatively. Similarly, at some point a child moves from not being able to think abstractly about the world to being able to do so. This is a qualitative, discontinuous change in development rather than a quantitative, continuous change.

Evaluating the Developmental Issues

Most life-span developmentalists acknowledge that development is not all nature or all nurture, not all stability or all change, and not all continuity or all discontinuity. Nature and nurture, stability and change, continuity and discontinuity characterize development throughout the human life span (Greenberg, 2021; Lewis, Al-Shawaf, & Buss, 2021). Although most developmentalists do not take extreme positions on these three important issues, however, there is spirited debate regarding how strongly development is influenced by each of them (Cowan & Smith, 2021; Landis & Bhawuk, 2021).

3 Theories of Development

LG3 Describe the main theories of human development.

Psychoanalytic Theories | Cognitive Theories | Behavioral and Social Cognitive Theories | Ethological Theory | Ecological Theory | An Eclectic Theoretical Orientation

How can we answer questions about the roles of nature and nurture, stability and change, and continuity and discontinuity in development? How can we determine, for example, whether special care can repair the harm inflicted by child neglect or whether memory loss in older adults can be prevented? The scientific method is the best tool we have to answer such questions (Smith & Davis, 2016).

The *scientific method* is essentially a four-step process: (1) conceptualize a process or problem to be studied; (2) collect research information (data); (3) analyze data; and (4) draw conclusions.

In step 1, when researchers are formulating a problem to study, they often draw on theories and develop hypotheses. A **theory** is an interrelated, coherent set of ideas that helps to explain phenomena and make predictions. It may suggest **hypotheses,** which are specific assertions and predictions that can be tested. For example, a theory on mentoring might state that sustained support and guidance from an adult improve the lives of children from impoverished backgrounds because the mentor gives the children opportunities to observe and imitate the behavior and strategies of the mentor.

This section outlines key aspects of five theoretical orientations to development: psychoanalytic, cognitive, behavioral and social cognitive, ethological, and ecological. Each contributes an important piece to the life-span development puzzle. Although the theories disagree about certain aspects of development, many of their ideas are complementary rather than contradictory. Together they let us see the total landscape of life-span development in all its richness.

Science refines everyday thinking.

theory An interrelated, coherent set of ideas that helps to explain phenomena and make predictions.

hypotheses Specific assumptions and predictions that can be tested to determine their accuracy.

psychoanalytic theories Theories that describe development as primarily unconscious and heavily colored by emotion. Behavior is merely a surface characteristic, and the symbolic workings of the mind must be analyzed to understand behavior. Early experiences with parents are emphasized.

PSYCHOANALYTIC THEORIES

Psychoanalytic theories describe development as primarily unconscious (beyond awareness) and heavily colored by emotion. Psychoanalytic theorists emphasize that behavior is merely a surface characteristic and that a true understanding of development requires analyzing the symbolic meanings of behavior and the deep inner workings of the mind. Psychoanalytic theorists also stress that early experiences with parents extensively shape development. These characteristics are highlighted in the main psychoanalytic theory, that of Sigmund Freud (1856–1939).

Freud's Theory As Freud listened to, probed, and analyzed his patients, he became convinced that their problems were the result of experiences early in life. He thought that as children grow up, their focus of pleasure and sexual impulses shifts from the mouth to the anus and eventually to the genitals. As a result, we go through five stages of psychosexual development: oral, anal, phallic, latency, and genital (see Figure 11). Our adult personality,

Oral Stage
Infant's pleasure centers on the mouth.
Birth to 1½ Years
Anal Stage
Child's pleasure focuses on the anus.
1½ to 3 Years
Phallic Stage
Child's pleasure focuses on the genitals.
3 to 6 Years
Latency Stage
Child represses sexual interest and develops social and intellectual skills.
6 Years to Puberty
Genital Stage
A time of sexual reawakening; source of sexual pleasure becomes someone outside the family.
Puberty Onward

FIGURE **11**

FREUDIAN STAGES. Because Freud emphasized sexual motivation, his stages of development are known as *psychosexual stages*. In his view, if the need for pleasure at any stage is either undergratified or overgratified, an individual may become *fixated,* or locked in, at that stage of development.

Erikson's Stages	Developmental Period
Integrity versus despair	Late adulthood (60s onward)
Generativity versus stagnation	Middle adulthood (40s, 50s)
Intimacy versus isolation	Early adulthood (20s, 30s)
Identity versus identity confusion	Adolescence (10 to 20 years)
Industry versus inferiority	Middle and late childhood (elementary school years, 6 years to puberty)
Initiative versus guilt	Early childhood (preschool years, 3 to 5 years)
Autonomy versus shame and doubt	Infancy (1 to 3 years)
Trust versus mistrust	Infancy (first year)

FIGURE **12**

ERIKSON'S EIGHT LIFE-SPAN STAGES. Like Freud, Erikson proposed that individuals go through distinct, universal stages of development. Thus, in terms of the continuity-discontinuity issue discussed in this chapter, both favor the discontinuity side of the debate. Notice that the timing of Erikson's first four stages is similar to that of Freud's stages. *What are the implications of saying that people go through stages of development?*

Erikson's theory Theory that proposes eight stages of human development. Each stage consists of a unique developmental task that confronts individuals with a crisis that must be resolved.

Freud (1917) claimed, is determined by the way we resolve conflicts between sources of pleasure at each stage and the demands of reality.

Freud's theory has been significantly revised by a number of psychoanalytic theorists. Many of today's psychoanalytic theorists argue that Freud overemphasized sexual instincts; they place more emphasis on cultural experiences as determinants of an individual's development. Unconscious thought remains a central theme, but conscious thought plays a greater role than Freud envisioned. Next, you will read about the ideas of an important revisionist of Freud's theories—Erik Erikson.

Erikson's Psychosocial Theory Erik Erikson recognized Freud's contributions but stressed that Freud misjudged some important dimensions of human development. For one thing, Erikson (1950, 1968) said we develop in psychosocial stages, rather than in psychosexual stages as Freud maintained. According to Freud, the primary motivation for human behavior is sexual in nature; according to Erikson, it is social and reflects a desire to affiliate with other people. According to Freud, our basic personality is shaped in the first five years of life; according to Erikson, developmental change occurs throughout the life span. Thus, in terms of the early-versus-later-experience issue described earlier in the chapter, Freud viewed early experiences as far more important than later experiences, whereas Erikson emphasized the importance of both early and later experiences.

In **Erikson's theory,** eight stages of development unfold as we go through life (see Figure 12). At each stage, a unique developmental task confronts individuals with a crisis that must be resolved. According to Erikson, this crisis is not a catastrophe but a turning point marked by both increased vulnerability and enhanced potential. The more successfully individuals resolve these crises, the healthier their development will be.

Trust versus mistrust is Erikson's first psychosocial stage, which is experienced in the first year of life. Trust in infancy sets the stage for a lifelong expectation that the world will be a good and pleasant place to live.

Autonomy versus shame and doubt is Erikson's second stage. This stage occurs in late infancy and toddlerhood (1 to 3 years). After gaining trust in their caregivers, infants begin to discover that their behavior is their own. They start to assert their sense of independence or autonomy. They realize their will. If infants and toddlers are restrained too much or punished too harshly, they are likely to develop a sense of shame and doubt.

Initiative versus guilt, Erikson's third stage of development, occurs during the preschool years. As preschool children encounter a widening social world, they face new challenges that require active, purposeful, responsible behavior. Feelings of guilt may arise, though, if the child is irresponsible and is made to feel too anxious.

Industry versus inferiority is Erikson's fourth developmental stage, occurring approximately in the elementary school years. Children now need to direct their energy toward mastering knowledge and intellectual skills. The negative outcome is that the child may develop a sense of inferiority—feeling incompetent and unproductive.

During the adolescent years, individuals face finding out who they are, what they are all about, and where they are going in life. This is Erikson's fifth developmental stage, *identity versus identity confusion.* If adolescents explore roles in a healthy manner and arrive at a positive path to follow in life, they achieve a positive identity; if they do not, identity confusion reigns.

Intimacy versus isolation is Erikson's sixth developmental stage, which individuals experience during early adulthood. At this time, individuals face the developmental task of forming intimate relationships. If young adults form healthy friendships and an intimate relationship with another, intimacy will be achieved; if not, isolation will result.

Generativity versus stagnation, Erikson's seventh developmental stage, occurs during middle adulthood. By generativity Erikson means primarily a concern for helping the younger generation to develop and lead useful lives. The feeling of having done nothing to help the next generation is stagnation.

Integrity versus despair is Erikson's eighth and final stage of development, which individuals experience in late adulthood. During this stage, a person reflects on the past. If the person's life review reveals a life well spent, integrity will be achieved; if not, the retrospective glances likely will yield doubt or gloom—the despair Erikson described.

We examine Erikson's theory in more detail in the chapter on "The Self, Identity, and Personality."

Evaluating Psychoanalytic Theories Contributions of psychoanalytic theories include an emphasis on a developmental framework, family relationships, and unconscious aspects of the mind. These theories have been criticized, however, for a lack of scientific support, too much emphasis on sexual underpinnings, and an image of people that is viewed as too negative.

COGNITIVE THEORIES

Whereas psychoanalytic theories stress the importance of the unconscious, cognitive theories emphasize conscious thoughts. Three important cognitive theories are Piaget's cognitive developmental theory, Vygotsky's sociocultural cognitive theory, and information-processing theory.

Piaget's Cognitive Developmental Theory **Piaget's theory** states that children go through four stages of cognitive development as they actively construct their understanding of the world. Two processes underlie this cognitive construction of the world: organization and adaptation. To make sense of our world, we organize our experiences. For example, we separate important ideas from less important ideas, and we connect one idea to another. In addition to organizing our observations and experiences, we adapt in response to new environmental demands.

Piaget's theory Theory stating that children actively construct their understanding of the world and go through four stages of cognitive development.

Jean Piaget (1954) also proposed that we go through four stages in understanding the world (see Figure 13). Each age-related stage consists of a distinct way of thinking, a *different way* of understanding the world. Thus, according to Piaget, the child's cognition is *qualitatively different* in one stage compared with another. What are Piaget's four stages of cognitive development?

The *sensorimotor stage,* which lasts from birth to about 2 years of age, is the first Piagetian stage. In this stage, infants construct an understanding of the world by coordinating sensory experiences (such as seeing and hearing) with physical, motoric actions—hence the term *sensorimotor.*

The *preoperational stage,* which lasts from approximately 2 to 7 years of age, is Piaget's second stage. In this stage, children begin to go beyond simply connecting sensory information with physical action and represent the world with words, images, and drawings. However, according to Piaget, preschool children still lack the ability to perform what he calls operations, which are internalized mental actions that allow children to do mentally what they previously could only do physically. For example, if you imagine putting two sticks together to see whether they would be as long as another stick, without actually moving the sticks, you are performing a concrete operation.

The *concrete operational stage,* which lasts from approximately 7 to 11 years of age, is the third Piagetian stage. In this stage, children can perform operations that involve objects, and they can reason logically when the reasoning can be applied to specific or concrete examples. For instance, concrete operational thinkers cannot imagine the steps necessary to complete an algebraic equation, which is too abstract for thinking at this stage of development.

The *formal operational stage,* which appears between the ages of 11 and 15 and continues through adulthood, is Piaget's fourth and final stage. In this stage, individuals move beyond concrete experiences and think in abstract and more logical terms. As part of thinking more abstractly, adolescents develop images of ideal circumstances. They might think about what an ideal parent is like and compare their parents to this ideal standard. They begin to entertain possibilities for the future and are fascinated with what they can become. In solving problems, they become more systematic, developing hypotheses about why something is happening the way it is and then testing these hypotheses. We examine Piaget's cognitive developmental theory in more detail in the chapter on "Cognitive Developmental Approaches."

Jean Piaget, the famous Swiss developmental psychologist, changed the way we think about the development of children's minds. *What are some key ideas in Piaget's theory?*

Vygotsky's theory Sociocultural cognitive theory that emphasizes how culture and social interaction guide cognitive development.

Lev Vygotsky was born the same year as Piaget, but he died much earlier, at the age of 37. There is considerable interest today in Vygotsky's sociocultural cognitive theory of child development. *What are some key characteristics of Vygotsky's theory?*
A.R. Lauria / Dr. Michael Cole, Laboratory of Human Cognition, University of California, San Diego

Vygotsky's Sociocultural Cognitive Theory

Like Piaget, the Russian developmentalist Lev Vygotsky (1896–1934) maintained that children actively construct their knowledge. However, Vygotsky (1962) gave social interaction and culture far more important roles in cognitive development than Piaget did. **Vygotsky's theory** is a sociocultural cognitive theory that emphasizes how culture and social interaction guide cognitive development.

Vygotsky portrayed the child's development as inseparable from social and cultural activities (Daniels, 2017). He argued that cognitive development involves learning to use the inventions of society, such as language, mathematical systems, and memory strategies. Thus, in one culture, children might learn to count with the help of a computer; in another, they might learn by using beads. According to Vygotsky, children's social interaction with more-skilled adults and peers is indispensable to their cognitive development (Holzman, 2017). Through this interaction, they learn to use the tools that will help them adapt and be successful in their culture (Daniels, 2017). In the chapter on "Cognitive Developmental Approaches," we examine ideas about learning and teaching that are based on Vygotsky's theory.

The Information-Processing Theory

Information-processing theory emphasizes that individuals manipulate information, monitor it, and strategize about it. Unlike Piaget's theory, but like Vygotsky's theory, information-processing theory does not describe development as stage-like. Instead, according to this theory, individuals develop a gradually increasing capacity for processing information, which allows them to acquire increasingly complex knowledge and skills (Gordon & others, 2020).

Robert Siegler (2006, 2013), a leading expert on children's information processing, states that thinking is information processing. In other words, when individuals perceive, encode, represent, store, and retrieve information, they are thinking. Siegler (2017) emphasizes that an

important aspect of development is learning good strategies for processing information. For example, becoming a better reader might involve learning to monitor the key themes of the material being read. In the chapter on "Information Processing," we explore the information-processing approach in greater depth.

Siegler (2006) also argues that the best way to understand how children learn is to observe them while they are learning. He emphasizes the importance of using the *microgenetic method* to obtain detailed information about processing mechanisms as they are occurring moment to moment. Siegler concludes that most research methods indirectly assess cognitive change, being more like snapshots than movies. The microgenetic method seeks to discover not just what children know but the cognitive processes involved in how they acquired the knowledge (Miller, 2016). A number of microgenetic studies have focused on a specific aspect of academic learning, such as how children learn whole number arithmetic, fractions, and other math skills (Siegler & Alibali, 2020).

David Cook/www.blueshiftstudios.co.uk/Alamy Stock Photo

Evaluating Cognitive Theories Contributions of cognitive theories include a positive view of development and an emphasis on the active construction of understanding. Criticisms include skepticism about the pureness of Piaget's stages and insufficient attention given to individual variations.

BEHAVIORAL AND SOCIAL COGNITIVE THEORIES

Behaviorism essentially holds that we can study scientifically only what we can directly observe and measure. Out of the behavioral tradition grew the belief that development is observable behavior that we can learn through experience with the environment (Schunk, 2020). In terms of the continuity-discontinuity issue discussed earlier in this chapter, the behavioral and social cognitive theories emphasize continuity in development and argue that development does not occur in stage-like fashion. Let's explore two versions of behaviorism: Skinner's operant conditioning and Bandura's social cognitive theory.

information-processing theory Theory emphasizing that individuals manipulate information, monitor it, and strategize about it. Central to this theory are the processes of memory and thinking.

social cognitive theory Theoretical view that behavior, environment, and cognition are the key factors in development.

Skinner's Operant Conditioning According to B. F. Skinner (1904–1990), through *operant conditioning* the consequences of a behavior produce changes in the probability of the behavior's occurrence. A behavior followed by a rewarding stimulus is more likely to recur, whereas a behavior followed by a punishing stimulus is less likely to recur. For example, when an adult smiles at a child after the child has done something, the child is more likely to engage in that behavior again than if the adult gives the child a disapproving look.

In Skinner's (1938) view, such rewards and punishments shape development. For Skinner the key aspect of development is behavior, not thoughts and feelings. He emphasized that development consists of the pattern of behavioral changes that are brought about by rewards and punishments. For example, Skinner would say that shy people learned to be shy as a result of experiences they had while growing up. It follows that modifications in an environment can help a shy person become more socially oriented.

B. F. Skinner was a tinkerer who liked to make new gadgets. The younger of his two daughters, Deborah, spent much of her infancy in Skinner's enclosed Air-Crib, which he invented because he wanted to ensure her comfort while minimizing the need for heavy blankets and pajamas. The Air-Crib was temperature controlled. Debbie, shown here as a child with her parents, is currently a successful artist, married and living in London. *What do you think about Skinner's Air-Crib?*
AP Images

Bandura's Social Cognitive Theory Some psychologists agree with the behaviorists' notion that development is learned and is influenced strongly by environmental interactions. However, unlike Skinner, they also see cognition as important in understanding development (Mischel, 2014). **Social cognitive theory** holds that behavior, environment, and cognition are the key factors in development.

American psychologist Albert Bandura (1925–) is the leading architect of social cognitive theory. Bandura (2001, 2015, 2018) emphasizes that cognitive processes have important links with the environment and behavior. His early research program focused heavily on *observational learning* (also called *imitation,* or *modeling*), which is learning that occurs through observing what

Albert Bandura has been one of the leading architects of social cognitive theory. *How does Bandura's theory differ from Skinner's?*

developmental **connection**
Achievement
Bandura emphasizes that self-efficacy is a key person/cognitive factor in achievement. Connect to "Schools, Achievement, and Work."

ethology Theory stressing that behavior is strongly influenced by biology, is tied to evolution, and is characterized by critical or sensitive periods.

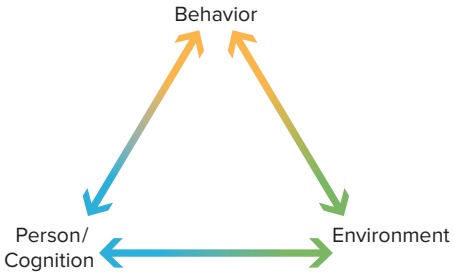

FIGURE **14**
BANDURA'S SOCIAL COGNITIVE MODEL. The arrows illustrate how relations between behavior, person/cognition, and environment are reciprocal rather than one-way. Person/cognition refers to cognitive processes (for example, thinking and planning) and personal characteristics (for example, believing that you can control your experiences).

others do. For example, a young boy might observe his father yelling in anger and treating other people with hostility; with his peers, the young boy later acts very aggressively, showing the same characteristics as his father's behavior. Social cognitive theorists stress that people acquire a wide range of behaviors, thoughts, and feelings through observing others' behavior and that these observations form an important part of life-span development.

What is *cognitive* about observational learning in Bandura's view? He proposes that people cognitively represent the behavior of others and then sometimes adopt this behavior themselves.

Bandura's (2001, 2015, 2018) model of learning and development includes three elements: behavior, the person/cognition, and the environment. An individual's sense of being in control of his or her success is an example of a person factor; strategies are an example of a cognitive factor. Recently, Bandura (2018) described *forethought* as a key cognitive factor in his social cognitive theory. When engaging in forethought, individuals guide and motivate themselves by creating action plans, formulating goals, and visualizing positive outcomes of their actions. As shown in Figure 14, behavior, person/cognition, and environmental factors operate interactively.

Further discussion of Bandura's social cognitive theory appears in the chapter on "Schools, Achievement, and Work."

Evaluating Behavioral and Social Cognitive Theories Contributions of the behavioral and social cognitive theories include an emphasis on scientific research and environmental determinants of behavior. These theories have been criticized for deemphasizing the role of cognition (Skinner) and giving inadequate attention to developmental changes.

ETHOLOGICAL THEORY

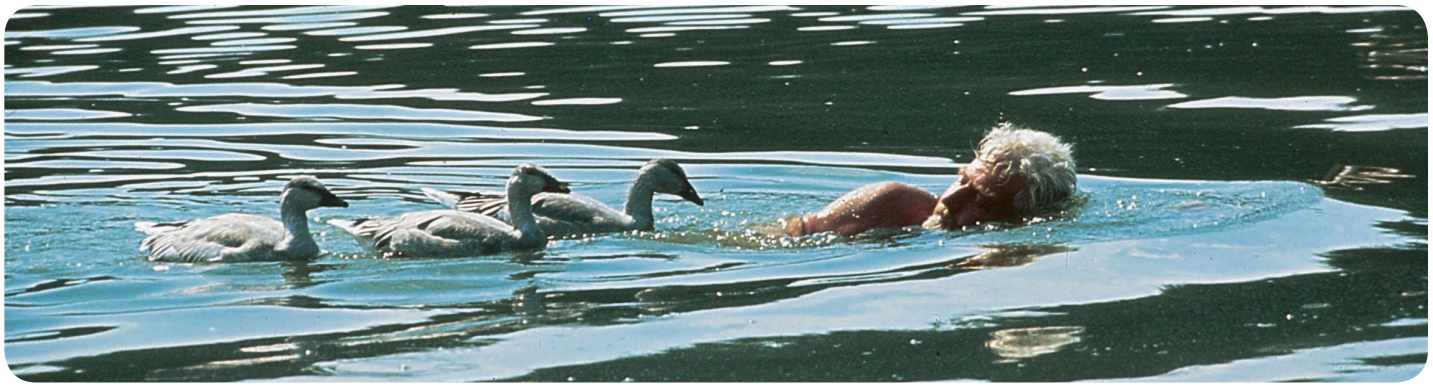
Ethology stresses that behavior is strongly influenced by biology, is tied to evolution, and is characterized by critical or sensitive periods. These are specific time frames during which, according to ethologists, the presence or absence of certain experiences has a long-lasting influence on individuals.

European zoologist Konrad Lorenz (1903–1989) helped bring ethology to prominence. In his best-known research, Lorenz (1965) studied the behavior of greylag geese, which will follow their mothers as soon as they hatch. Lorenz separated the eggs laid by one goose into two groups. One group he returned to the goose to be hatched by her. The other group was hatched in an incubator. The goslings in the first group performed as predicted. They followed their mother as soon as they hatched. However, those in the second group, which saw Lorenz when they first hatched, followed him everywhere as though he were their mother. Lorenz marked the goslings and then placed both groups under a box. Mother goose and "mother" Lorenz stood aside as the box was lifted. Each group of goslings went directly to its "mother." Lorenz called this process *imprinting:* the rapid, innate learning that involves attachment to the first moving object that is seen.

John Bowlby (1969, 1989) illustrated an important application of ethological theory to human development. Bowlby stressed that attachment to a caregiver over the first year of life has important consequences throughout the life span. In his view, if this attachment is positive and secure, the individual will likely develop positively in childhood and adulthood. If the attachment is negative and insecure, life-span development will likely not be optimal. In the chapter on "Emotional Development," we explore the concept of infant attachment in much greater detail.

In Lorenz's view, imprinting needs to take place at a certain, very early time in the life of the animal, or else it will not take place. This point in time is called a *critical period*. A related concept involves the existence of a *sensitive period,* and an example of this is the time during infancy when, according to Bowlby, attachment should occur in order to promote optimal development of social relationships.

Another theory that emphasizes biological foundations of development—evolutionary psychology (Lewis, Al-Shawaf, & Buss, 2021)—is presented in the chapter on "Biological Beginnings," along with views on the role of heredity in development (Sallis, Smith, & Munato, 2021). In addition, we examine a number of biological theories of aging in the chapter on "Physical Development and Biological Aging" (Entringer & Epel, 2020).



Konrad Lorenz, a pioneering student of animal behavior, is followed through the water by three imprinted greylag geese. Describe Lorenz's experiment with the geese. *Do you think his experiment would have the same results with human babies? Explain.*
Nina Leen/The LIFE Picture Collection/Getty Images

Contributions of ethological theory include its focus on the biological and evolutionary basis of development and its use of careful observations in naturalistic settings. Ethological theory has been criticized for its overemphasis on biological foundations and lack of flexibility regarding the concepts of critical and sensitive periods.

ECOLOGICAL THEORY

While ethological theory stresses biological factors, ecological theory emphasizes environmental factors. One ecological theory that has important implications for understanding life-span development was created by Urie Bronfenbrenner (1917–2005).

Bronfenbrenner's ecological theory (1986, 2004; Bronfenbrenner & Morris, 1998, 2006) holds that development reflects the influence of several environmental systems. The theory identifies five environmental systems: microsystem, mesosystem, exosystem, macrosystem, and chronosystem (see Figure 15).

The *microsystem* is the setting in which the individual lives. Contexts within it include the person's family, peers, school, and neighborhood. It is in the microsystem that the most direct interactions with social agents take place—with parents, friends, and teachers, for example. The individual is not a passive recipient of experiences in these settings, but someone who helps to construct the settings.

The *mesosystem* involves relations between microsystems or connections between contexts. Examples are the relationship of family experiences to school experiences, school experiences to church experiences, and family experiences to peer experiences. For example, children whose parents have rejected them may have difficulty developing positive relations with teachers.

The *exosystem* consists of links between the individual's immediate context and a social setting in which the individual does not play an active role. For example, a father's or child's experience at home may be influenced by a mother's experiences at work. The mother might receive a promotion that requires more travel, which might increase conflict with her husband and change patterns of interaction with their child.

The *macrosystem* involves the culture in which individuals live. Remember from earlier in the chapter that culture refers to the behavior patterns, beliefs, and all other products of a group of people that are passed on from generation to generation. Remember also that cross-cultural studies—the comparison of one culture with one or more other cultures—provide information about the generality of development.

The *chronosystem* consists of the patterning of environmental events and transitions over the life course, as well as sociohistorical circumstances. For example, divorce is one

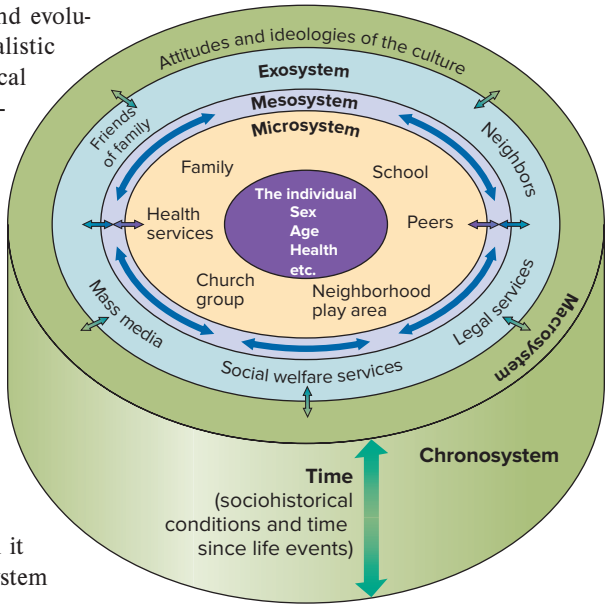


FIGURE **15**

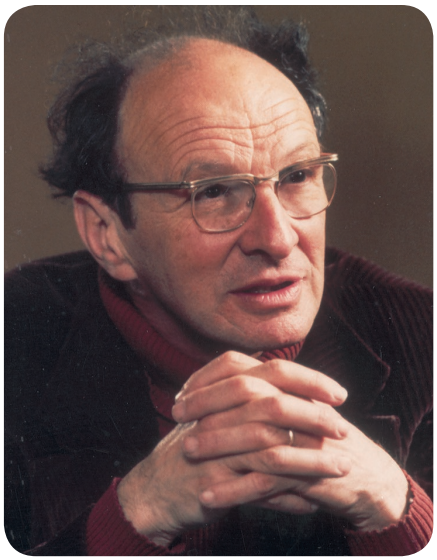
BRONFENBRENNER'S ECOLOGICAL THEORY OF DEVELOPMENT. Bronfenbrenner's ecological theory describes five environmental systems: microsystem, mesosystem, exosystem, macrosystem, and chronosystem.

Bronfenbrenner's ecological theory Bronfenbrenner's environmental systems theory that focuses on five environmental systems: microsystem, mesosystem, exosystem, macrosystem, and chronosystem.



Urie Bronfenbrenner developed ecological theory, a perspective that is receiving increased attention today. His theory emphasizes the importance of both micro and macro dimensions of the environment in which the child lives.
Courtesy of Cornell University Photography

transition. Researchers have found that the negative effects of divorce on children often peak during the first year after the divorce (Hetherington, 1993, 2006). By two years after the divorce, family interaction is more stable. As an example of sociohistorical circumstances, consider how the opportunities for women to pursue a career have increased since the 1960s.

Bronfenbrenner (2004; Bronfenbrenner & Morris, 2006) subsequently added biological influences to his theory, describing it as a bioecological theory. Nonetheless, it is still dominated by ecological, environmental contexts.

Contributions of the theory include its systematic examination of micro and macro dimensions of environmental systems, and its attention to connections between environmental systems. A further contribution of Bronfenbrenner's theory is an emphasis on a range of social contexts beyond the family, such as neighborhood, religious community, school, workplace, and culture as influential in children's development (Worrell, Hughes, & Dixson, 2021). The theory has been criticized for giving inadequate attention to the influence of biological and cognitive factors.

AN ECLECTIC THEORETICAL ORIENTATION

No single theory described in this chapter can explain entirely the rich complexity of life-span development, but each has contributed to our understanding of development. Psychoanalytic theory best explains the workings of the unconscious mind. Erikson's theory best describes the changes that occur in adult development. Piaget's, Vygotsky's, and the information-processing views provide the most complete description of cognitive development. The behavioral and social cognitive and ecological theories have been the most adept at examining the environmental determinants of development. The ethological theories have highlighted biology's role and the importance of sensitive periods in development.

In short, although theories can be helpful guides, relying on a single theory to explain development probably would be a mistake. Our solution to this dilemma is to take an **eclectic theoretical orientation**—rather than following a single theoretical approach, an eclectic approach selects from each theory whatever is considered its best features. Figure 16 compares the main theoretical perspectives in terms of how they view important issues in human development.

eclectic theoretical orientation An orientation that does not follow any one theoretical approach but rather selects from each theory whatever is considered best in it.

THEORY	ISSUES	
	Continuity/discontinuity, early versus later experiences	**Biological and environmental factors**
Psychoanalytic	Discontinuity between stages—continuity between early experiences and later development; early experiences very important; later changes in development emphasized in Erikson's theory	Freud's biological determination interacting with early family experiences; Erikson's more balanced biological-cultural interaction perspective
Cognitive	Discontinuity between stages in Piaget's theory; continuity between early experiences and later development in Piaget's and Vygotsky's theories; no stages in Vygotsky's theory or information-processing theory	Piaget's emphasis on interaction and adaptation; environment provides the setting for cognitive structures to develop; information-processing view has not addressed this issue extensively but mainly emphasizes biological-environmental interaction
Behavioral and social cognitive	Continuity (no stages); experience at all points of development important	Environment viewed as the cause of behavior in both views
Ethological	Discontinuity but no stages; critical or sensitive periods emphasized; early experiences very important	Strong biological view
Ecological	Little attention to continuity/discontinuity; change emphasized more than stability	Strong environmental view

- Which of the life-span theories do you think best explains your own development? Why?

4 Research on Life-Span Development

LG4 Explain how research on life-span development is conducted.

Methods for Collecting Data | Research Designs | Time Span of Research | Conducting Ethical Research | Minimizing Bias

If they follow an eclectic orientation, how do scholars and researchers determine that one feature of a theory is somehow better than another? The scientific method discussed earlier in this chapter provides the guide. Through scientific research, they can test and refine the features of theories (Gravetter & others, 2021).

Generally, research in life-span development is designed to test hypotheses, which in some cases are derived from the theories just described. Through research, theories are modified to reflect new data, and occasionally new theories arise.

METHODS FOR COLLECTING DATA

Whether we are interested in studying attachment in infants, the cognitive skills of children, or social relationships in older adults, we can choose from several ways of collecting data. Here we consider the measures most often used, beginning with observation.

Observation Scientific observation requires an important set of skills. For observations to be effective, they have to be systematic. We need to have some idea of what we are looking for. We have to know whom we are observing, when and where we will observe, how we will make our observations, and how we will record them.

Where should we make our observations? We have two choices: the laboratory and the everyday world.

When we observe scientifically, we often need to control certain factors that determine behavior but are not the focus of our inquiry (Graziano & Raulin, 2020). For this reason, some research in life-span development is conducted in a **laboratory,** a controlled setting where many of the complex factors of the "real world" are absent. For example, suppose you want to observe how children react when they see other people act aggressively. If you observe

laboratory A controlled setting from which many of the complex factors of the "real world" have been removed.

What are some important strategies in conducting observational research with children?
Charles Fox/Philadelphia Inquirer/MCT/Landov Images

children in their homes or schools, you have no control over how much aggression the children observe, what kind of aggression they see, which people they see acting aggressively, or how other people treat the children. In contrast, if you observe the children in a laboratory, you can control these and other factors and therefore have more confidence about how to interpret your observations.

Laboratory research does have some drawbacks, however, including the following:

- It is almost impossible to conduct research without the participants knowing they are being studied.
- The laboratory setting is unnatural and therefore can cause the participants to behave unnaturally.
- People who are willing to come to a university laboratory may not fairly represent groups from diverse cultural backgrounds.
- People who are unfamiliar with university settings may be intimidated by the laboratory atmosphere.

Naturalistic observation provides insights that sometimes cannot be obtained in the laboratory (Neuman, 2020). **Naturalistic observation** means observing behavior in real-world settings, making no effort to manipulate or control the situation. Life-span researchers conduct naturalistic observations at sporting events, child-care centers, schools, work settings, malls, and other places people live in and frequent.

Naturalistic observation was used in one study that focused on conversations in a children's science museum (Crowley & others, 2001). When visiting exhibits at the science museum, parents were three times as likely to engage boys as girls in explanatory talk. This finding suggests a gender bias that encourages boys more than girls to be interested in science (see Figure 17).

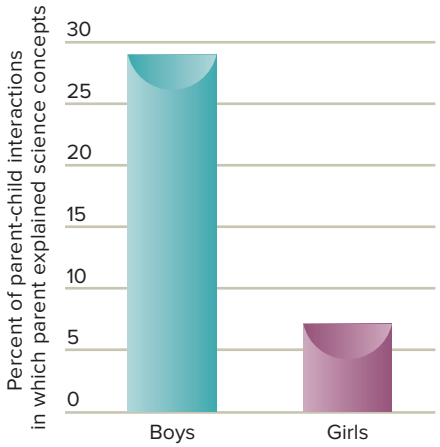

FIGURE **17**

PARENTS' EXPLANATIONS OF SCIENCE TO SONS AND DAUGHTERS AT A SCIENCE MUSEUM. In a naturalistic observation study at a children's science museum, parents were three times more likely to explain science to boys than to girls (Crowley & others, 2001). The gender difference occurred regardless of whether the father, the mother, or both parents were with the child, although the gender difference was greatest for fathers' science explanations to sons and daughters.

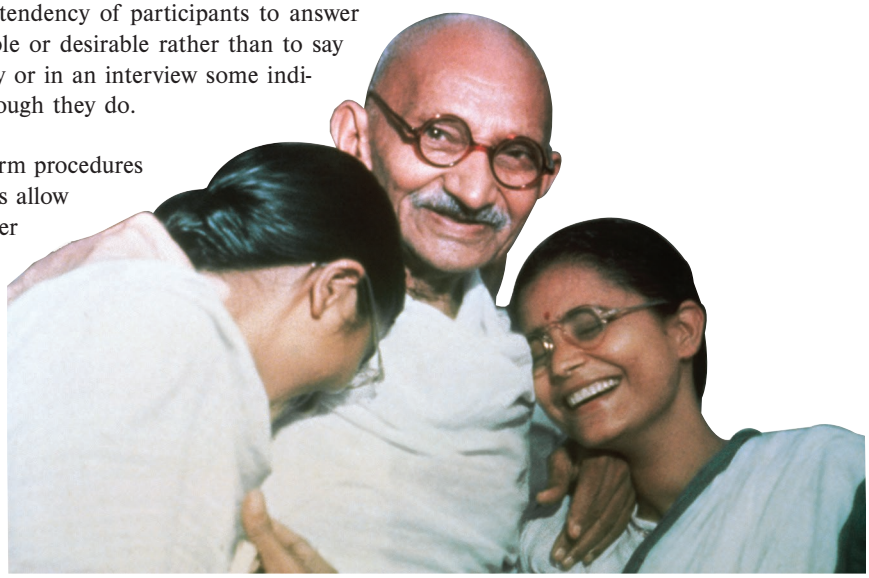
naturalistic observation Observing behavior in real-world settings.

Survey and Interview

Sometimes the best and quickest way to get information about people is to ask them for it. One technique is to *interview* them directly. A related method is the survey—sometimes referred to as a *questionnaire*—which is especially useful when information from many people is needed (Neuman, 2020). A standard set of questions is used to obtain people's self-reported attitudes or beliefs about a particular topic. In a good survey, the questions are clear and unbiased, allowing respondents to answer unambiguously.

Surveys and interviews can be used to study a wide range of topics, from religious beliefs to sexual habits to attitudes about gun control to beliefs about how to improve schools. Surveys and interviews may be conducted in person, over the telephone, and over the Internet.

One problem with surveys and interviews is the tendency of participants to answer questions in a way that they think is socially acceptable or desirable rather than to say what they truly think or feel. For example, on a survey or in an interview some individuals might say that they do not take drugs even though they do.



Mahatma Gandhi was the spiritual leader of India in the middle of the 20th century. Erik Erikson conducted an extensive case study of Gandhi's life to determine what contributed to his identity development. *What are some limitations of the case study approach?*
Bettmann/Getty Images

Standardized Test A **standardized test** has uniform procedures for administration and scoring. Many standardized tests allow a person's performance to be compared with that of other individuals; thus, they provide information about individual differences among people (Cohen, 2022). One example is the Stanford-Binet intelligence test, which is described in the chapter on "Intelligence." Your score on the Stanford-Binet test tells you how your performance compares with that of thousands of other people who have taken the test.

One criticism of standardized tests is that they assume a person's behavior is consistent and stable, although personality and intelligence—two primary targets of standardized testing—can vary with the situation. For example, a person may perform poorly on a standardized intelligence test in an office setting but score much higher at home, where he or she is less anxious.

Case Study A **case study** is an in-depth look at a single individual. Case studies are performed mainly by mental health professionals when, for either practical or ethical reasons, the unique aspects of an individual's life cannot be duplicated and tested in other individuals. A case study provides information about one person's experiences; it may focus on nearly any aspect of the subject's life that helps the researcher understand the person's mind, behavior, or other attributes. In other chapters, we discuss vivid case studies, such as that of Michael Rehbein, who had much of the left side of his brain removed at 7 years of age to end severe epileptic seizures.

A case study can provide a dramatic, in-depth portrayal of an individual's life, but we must be cautious when generalizing from this information. The subject of a case study is unique, with a genetic makeup and personal history that no one else shares. In addition, case studies involve judgments of unknown reliability. Researchers who conduct case studies rarely check to see if other professionals agree with their observations or findings.

standardized test A test with uniform procedures for administration and scoring. Many standardized tests allow a person's performance to be compared with the performance of other individuals.

case study An in-depth look at a single individual.

Physiological Measures Researchers are increasingly using physiological measures when they study development at different points in the life span. Hormone levels are increasingly examined in developmental research. Cortisol is a hormone produced by the adrenal gland that is linked to the body's stress level and has been measured in studies of temperament, emotional reactivity, mood, and peer relations (Jahangard & others, 2019). Also, as puberty unfolds, the blood levels of certain hormones increase. To determine the nature of these hormonal changes, researchers analyze blood samples from adolescent volunteers (Bae & others, 2019).

Another physiological measure that is increasingly being used is neuroimaging, especially *functional magnetic resonance imaging* (fMRI), in which electromagnetic waves are used to construct images of a person's brain tissue and biochemical activity (Kirmayer & others, 2021). Figure 18

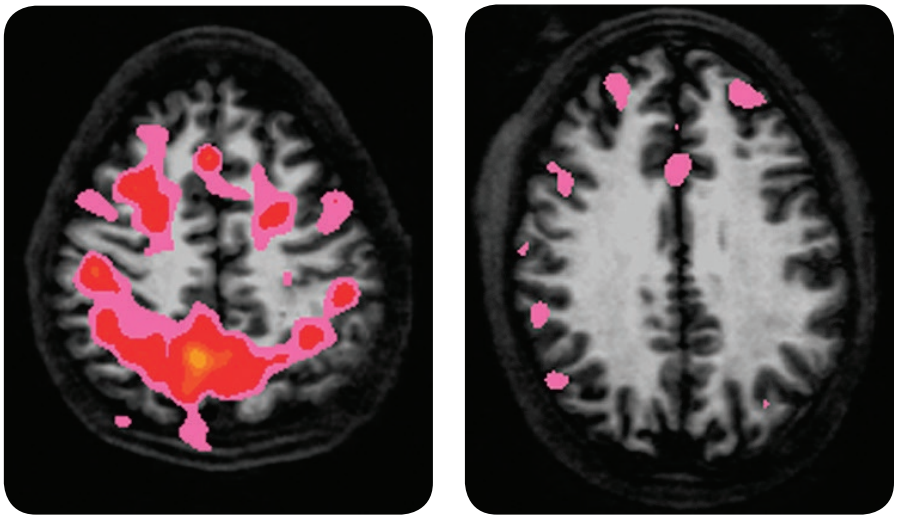


FIGURE **18**

BRAIN IMAGING OF 15-YEAR-OLD ADOLESCENTS. These two brain images indicate how alcohol can influence the functioning of an adolescent's brain. Notice the pink and red coloring (which indicates effective brain functioning involving memory) in the brain of a 15-year-old nondrinker (*left*) while engaging in a memory task, and compare it with the lack of those colors in the brain of a 15-year-old heavy drinker (*right*) under the influence of alcohol.
Dr. Susan F. Tapert, University of California, San Diego

compares the brain images of two adolescents—one a nondrinker and the other a heavy drinker—while they are engaged in a memory task.

Electroencephalography (EEG) is a physiological measure that has been used for many decades to monitor overall electrical charges in the brain (Richards & Conte, 2021). Recent electroencephalography research includes studies of infants' attention and memory (Bell & Broomell, 2021).

Heart rate has been used as an indicator of infants' and children's development of perception, attention, and memory, as well as in research on physical fitness and obesity (Redon & others, 2020). Further, heart rate has been used as an index of different aspects of emotional development, such as inhibition, stress, and anxiety (Jafarova & others, 2020).

Eye movement also is increasingly being assessed to learn more about perceptual development and other developmental topics. Sophisticated eye-tracking equipment is used to provide more detailed information about infants' perception (Maurer, 2021), attention (Amso & Tummeltshammer, 2021), face processing (Krasotkina & others, 2020), cognitive exploration (D'Souza & others, 2020), language acquisition (Egger, Rowland, & Bergmann, 2020), and the development of autism (Falck-Ytter & Jones, 2021).

Yet another dramatic change in physiological methods is the advancement in methods to assess the actual units of hereditary information—genes—in studies of biological influences on development (Brooker, 2021). For example, recent advances in gene assessment have identified several specific genes that are linked to childhood obesity (Saeed & others, 2020). And in a later chapter you will read about the role of the ApoE4 gene in Alzheimer disease (Montagne, Nation, & Ziokovic, 2020).

RESEARCH DESIGNS

In conducting research on life-span development, in addition to having a method for collecting data, you also need a research design. There are three main types of research designs: descriptive, correlational, and experimental.

Descriptive Research

All of the data-collection methods that we have discussed can be used in **descriptive research,** which aims to observe and record behavior. For example, a researcher might observe the extent to which people are altruistic or aggressive toward each other. By itself, descriptive research cannot prove what causes some phenomenon, but it can reveal important information about people's behavior (Neuman, 2020).

Correlational Research

In contrast with descriptive research, correlational research goes beyond describing phenomena to provide information that will help us to predict how people will behave (Gravetter & others, 2021). In **correlational research,** the goal is to describe the strength of the relationship between two or more events or characteristics. The more strongly the two events are correlated (or related or associated), the more effectively we can predict one event from the other.

For example, to find out whether children of permissive parents have less self-control than other children, you would need to carefully record observations of parents' permissiveness and their children's self-control. You might observe that the higher a parent was in permissiveness, the lower the child was in self-control. You would then analyze these data statistically to yield a numerical measure, called a **correlation coefficient,** a number based on a statistical analysis that is used to describe the degree of association between two variables. The correlation coefficient ranges from −1.00 to +1.00. A negative number means an inverse (reversed) relation. In the example just given, you might find an inverse correlation between permissive parenting and children's self-control, with a coefficient of, say, −.30. By contrast, you might find a positive correlation of +.30 between parental monitoring of children and children's self-control.

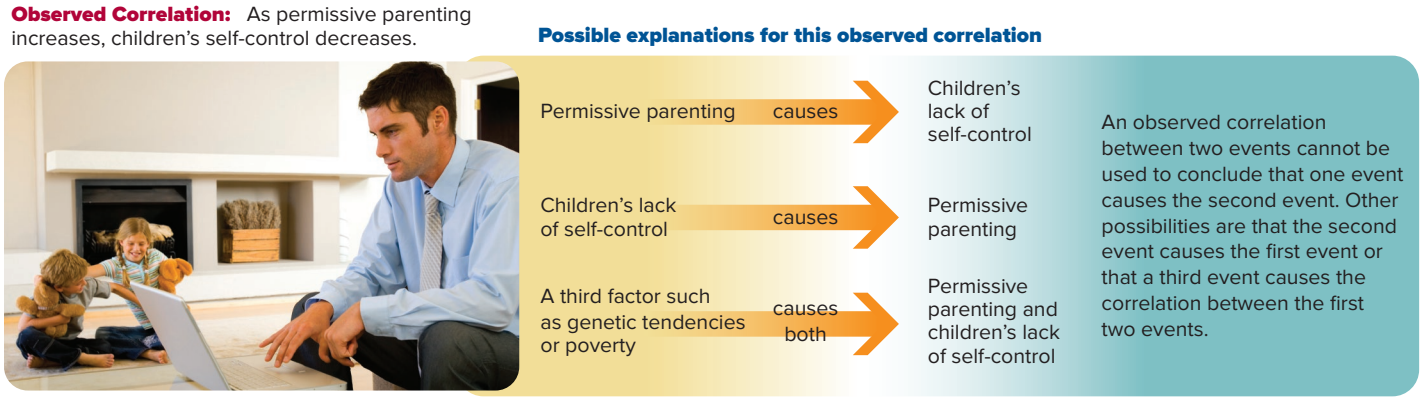
descriptive research A type of research that aims to observe and record behavior.

correlational research A type of research that strives to describe the strength of the relationship between two or more events or characteristics.

correlation coefficient A number based on a statistical analysis that is used to describe the degree of association between two variables.

The higher the correlation coefficient (whether positive or negative), the stronger the association between the two factors. A correlation of 0 means that there is no association between the factors. A correlation of −.40 is stronger than a correlation of +.20 because we disregard whether the correlation is positive or negative in determining the strength of the correlation.

A caution is in order, however. Correlation does not equal causation. The correlational finding just mentioned does not mean that permissive parenting necessarily causes low self-control in children. It could have that meaning, but it also could mean that a child's lack of self-control caused the parents to throw up their arms in despair and give up trying to control



Observed Correlation: As permissive parenting increases, children's self-control decreases.
Possible explanations for this observed correlation
Permissive parenting
causes
Children's lack of self-control
Children's lack of self-control
causes
Permissive parenting
A third factor such as genetic tendencies or poverty
causes both
Permissive parenting and children's lack of self-control
An observed correlation between two events cannot be used to conclude that one event causes the second event. Other possibilities are that the second event causes the first event or that a third event causes the correlation between the first two events.

FIGURE **19**

POSSIBLE EXPLANATIONS OF CORRELATIONAL DATA.
JupiterImages/Pixland/Getty Images

the child. It also could mean that other factors, such as heredity or poverty, caused the correlation between permissive parenting and low self-control in children. Figure 19 illustrates these possible interpretations of correlational data.

Experimental Research

To study causality, researchers turn to experimental research. An **experiment** is a carefully regulated procedure in which one or more factors believed to influence the behavior being studied are manipulated while all other factors are held constant. If the behavior under study changes when a factor is manipulated, the manipulated factor has caused the behavior to change (Christensen, Johnson, & Turner, 2020). In other words, the experiment has demonstrated cause and effect. The cause is the factor that was manipulated. The effect is the behavior that changed because of the manipulation. Nonexperimental research methods (descriptive and correlational research) cannot establish cause and effect because they do not involve manipulating factors in a controlled way.

experiment Carefully regulated procedure in which one or more factors believed to influence the behavior being studied are manipulated while all other factors are held constant.

Independent and Dependent Variables

Experiments include two types of changeable factors, or variables: independent and dependent. An *independent variable* is a manipulated, influential, experimental factor. It is a potential cause. The label "independent" is used because this variable can be manipulated independently of other factors to determine its effect. An experiment may include one independent variable or several of them.

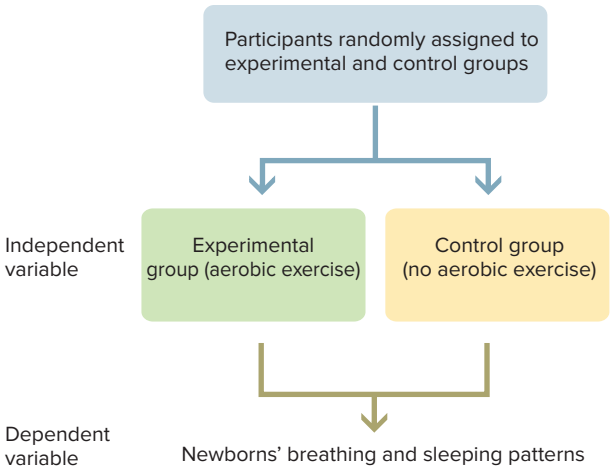
A *dependent variable* is a factor that can change in an experiment, in response to changes in the independent variable. As researchers manipulate the independent variable, they measure the dependent variable for any resulting effect.

For example, suppose that you are conducting a study to determine whether pregnant women could change the breathing and sleeping patterns of their newborn babies by engaging in aerobic exercise during pregnancy. You might require one group of pregnant women to engage in a certain amount and type of aerobic exercise each day while another group would not exercise; the aerobic exercise is thus the independent variable. When the infants are born, you would observe and measure their breathing and sleeping patterns. These patterns are the dependent variable, the factor that changes as the result of your manipulation.

Experimental and Control Groups

Experiments can involve one or more experimental groups and one or more control groups (Graziano & Raulin, 2020). An experimental group is a group whose experience is manipulated. A *control group* is a comparison group that resembles the experimental group as closely as possible and is treated in every way like the experimental group except for the manipulated factor (independent variable). The control group serves as a baseline against which the effects of the manipulated condition can be compared.

Random assignment is an important principle for deciding whether each participant will be placed in the experimental group or in the control group. Random assignment means that researchers assign participants to experimental and control groups by chance. It reduces the likelihood that the experiment's results will be due to any preexisting differences between groups. In the example of the effects of aerobic exercise by pregnant women on the breathing and sleeping patterns of their newborns, you would randomly assign half of the pregnant women to engage in aerobic exercise over a period of weeks (the experimental group) and the other half not to exercise during the same number of weeks (the control group). Figure 20 illustrates the nature of experimental research.



Participants randomly assigned to experimental and control groups
Independent variable
Experimental group (aerobic exercise)
Control group (no aerobic exercise)
Dependent variable
Newborns' breathing and sleeping patterns

FIGURE **20**

PRINCIPLES OF EXPERIMENTAL RESEARCH. Imagine that you decide to conduct an experimental study of the effects of aerobic exercise by pregnant women on their newborns' breathing and sleeping patterns. You would randomly assign pregnant women to experimental and control groups. The experimental-group women would engage in aerobic exercise over a specified number of sessions and weeks. The control group would not. Then, when the infants are born, you would assess their breathing and sleeping patterns. If the breathing and sleeping patterns of newborns whose mothers were in the experimental group are more positive than those of the control group, you would conclude that aerobic exercise caused the positive effects.

TIME SPAN OF RESEARCH

Researchers in life-span development have a special concern with studies that focus on the relation of age to some other variable. They have several options: Researchers can study different individuals of varying ages and compare them, or they can study the same individuals as they age over time.

Cross-Sectional Approach

The **cross-sectional approach** is a research strategy that simultaneously compares individuals of different ages. A typical cross-sectional study might include three groups of children: 5-year-olds, 8-year-olds, and 11-year-olds. Another study might include groups of 15-year-olds, 25-year-olds, and 45-year-olds. The groups can be compared with respect to a variety of dependent variables: IQ, memory, peer relations, attachment to parents, hormonal changes, and so on. All of these comparisons can be accomplished in a short time. In some studies, data are collected in a single day. Even in large-scale cross-sectional studies with hundreds of subjects, data collection does not usually take longer than several months to complete.

The main advantage of the cross-sectional study is that the researcher does not have to wait for the individuals to grow up or become older. Despite its efficiency, though, the cross-sectional approach has its drawbacks. It gives no information about how individuals change or about the stability of their characteristics. It can obscure the increases and decreases of development—the hills and valleys of growth and development. For example, a cross-sectional study of life satisfaction might reveal average increases and decreases, but it would not show how the life satisfaction of individual adults waxed and waned over the years. It also would not tell us whether the same adults who had positive or negative perceptions of life satisfaction in early adulthood maintained their relative degree of life satisfaction as they became middle-aged or older adults.

Longitudinal Approach

The **longitudinal approach** is a research strategy in which the same individuals are studied over a period of time, usually several years or more. For example, in a longitudinal study of life satisfaction, the same adults might be assessed periodically over a 70-year time span—at the ages of 20, 35, 45, 65, and 90, for example.

Longitudinal studies provide a wealth of information about vital issues such as stability and change in development and the importance of early experience for later development, but they do have drawbacks (Kramer & Rodgers, 2020). They are expensive and time consuming. The longer the study lasts, the more participants drop out—they move, get sick, lose interest, and so forth. The participants who remain may be dissimilar to those who drop out, biasing the outcome of the study. Those individuals who remain in a longitudinal study over a number of years may be more responsible and conformity-oriented, for example, or they might lead more stable lives.

Cohort Effects

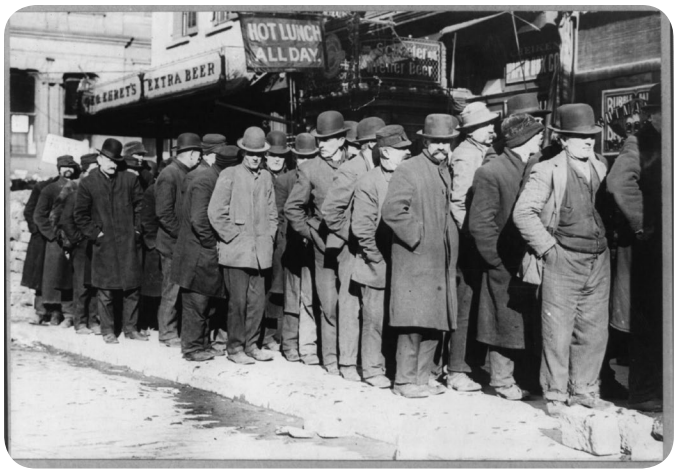
Earlier in our focus on characteristics of the life-span perspective on development, we described the importance of considering historical effects. An important term that is used in studying historical effects is *cohort*, a group of people who are born at a similar point in history and share similar experiences as a result, such as living through the Vietnam War or growing up in the same city around the same time. These shared experiences may produce a range of differences among cohorts (Vaz & others, 2021). For example, people who were teenagers during World War II are likely to differ from people who were teenagers during the booming 1990s in their educational opportunities and economic status, in how they were raised, and in their attitudes toward sex and religion. In life-span development research, **cohort effects** are due to a person's time of birth, era, or generation but not to actual age.

Cohort effects are important because they can powerfully affect the dependent measures in a study ostensibly concerned with age (Wu & others, 2020). Researchers have shown it is especially important to be aware of cohort effects when assessing adult intelligence (Schaie, 2013, 2016). Individuals born at different points in time—such as 1930, 1960, and 1990—have had varying opportunities for education. Individuals born in earlier years had less access to education, and this fact may have a significant effect on how this cohort performs on

cross-sectional approach A research strategy in which individuals of different ages are compared at one time.

longitudinal approach A research strategy in which the same individuals are studied over a period of time, usually several years or more.

cohort effects Characteristics attributable to a person's time of birth, era, or generation but not to actual age.



Cohort effects are due to a person's time of birth or generation but not actually to age. Think for a moment about growing up in (*a*) the Great Depression and (*b*) today. *How might your development be different depending on which of these time frames has dominated your life? How might generational experiences have affected your parents' lives? your grandparents' lives?*
(*Left*) Source: George Grantham Bain Collection/Library of Congress Prints and Photographs Division [LC-USZ62-63966].; (*right*) Jamie Grill/Blend Images/Corbis

intelligence tests. Some researchers have found that cross-sectional studies indicate more than 90 percent of cognitive decline in aging is due to a slowing of processing speed, whereas longitudinal studies reveal that 20 percent or less of cognitive decline is due to processing speed (MacDonald & Stawski, 2016). Further, in a recent study, older adults nowadays report fewer constraints than their counterparts 18 years ago, but younger adults report more constraints and lower mastery beliefs today than those 18 years ago (Drewelies & others, 2018).

Cross-sectional studies can show how different cohorts respond, but they can confuse age changes and cohort effects. Longitudinal studies are effective in studying age changes, but only within one cohort.

Various generations have been given labels by the popular culture. Figure 21 describes the labels of various generations, their historical periods, and the reasons for their labels.

How are today's generation Z/post-millennials experiencing youth differently from earlier generations?
Hero Images/Alamy Stock Photo

FIGURE 21
GENERATIONS, THEIR HISTORICAL PERIODS, AND CHARACTERISTICS

Generation	Historical Period	Reasons for Label
Generation Z/ Post-Millennials	Individuals born in 1997 and later	More immersed in a technological world, more ethnically diverse, and better educated than millennials. Become immersed in social media.
Millennials	Individuals born between 1981 and 1996	First generation to come of age and enter emerging adulthood (18 to 25 years of age) in the twenty-first century (the new millennium). Two main characteristics: (1) connection to technology, and (2) ethnic diversity.
Generation X	Individuals born between 1965 and 1980	Described as lacking an identity and savvy loners.
Baby Boomers	Individuals born between 1946 and 1964	Label used because this generation represents the spike in the number of babies born after World War II; the largest generation ever to enter late adulthood in the United States.
Silent Generation	Individuals born between 1928 and 1945	Children of the Great Depression and World War II; described as conformists and civic minded.

Until recently, the youngest generation was labeled *millennials,* and this group was recognized as being more technologically sophisticated and more ethnically diverse than earlier generations. However, the Pew Research Center, which has periodically assessed generational trends in recent decades, recently decided to describe millennials as anyone born between 1981 and 1996, with anyone born in 1997 or later as part of a new generation (Dimock, 2019). The name of this new generation has not yet been selected, but two potential names are *generation Z* and *post-millennial*. The oldest members of this new generation turned 23 in 2020, while the oldest millennials turned 39 in 2020. What characterizes this new Z/post-millennial generation? They are even more technologically sophisticated and ethnically diverse than millennials. These young people have technological devices that are always available and always on; they are immersed in social media; and they tend to communicate with others online and through mobile devices far more than in person. Also, generation Z/post-millennials are the best-educated generation ever: they are more likely to go to college and to have a college-educated parent than millennials are (Fry & Parker, 2018).

CONDUCTING ETHICAL RESEARCH

Ethics in research may affect you personally if you ever serve as a participant in a study. In that event, you need to know your rights as a participant and the responsibilities of researchers to assure that these rights are safeguarded.

If you ever become a researcher in life-span development yourself, you will need an even deeper understanding of ethics. Even if you only carry out experimental projects in psychology courses, you must consider the rights of the participants in those projects. A student might think, "I volunteer in a home for individuals with intellectual disabilities several hours per week. I can use the residents of the home in my study to see if a particular treatment helps improve their memory for everyday tasks." But without proper permissions, the most well-meaning and considerate studies still violate the rights of the participants (Neuman, 2020).

Today, proposed research at colleges and universities must pass the scrutiny of a research ethics committee before the research can begin. In addition, the American Psychological Association (APA) has developed ethics guidelines for its members. The code of ethics instructs psychologists to protect their participants from mental and physical harm. The participants' best interests need to be kept foremost in the researcher's mind. APA's guidelines address four important issues:

1. *Informed consent*. All participants must know what their research participation will involve and what risks might develop. Even after informed consent is given, participants must retain the right to withdraw from the study at any time and for any reason.
2. *Confidentiality.* Researchers are responsible for keeping all of the data they gather on individuals completely confidential and, when possible, completely anonymous.
3. *Debriefing.* After the study has been completed, participants should be informed of its purpose and the methods that were used. In most cases, the experimenter also can inform participants in a general manner beforehand about the purpose of the research without leading participants to behave in a way they think the experimenter is expecting.
4. *Deception.* In some circumstances, telling the participants beforehand what the research study is about substantially alters the participants' behavior and invalidates the researcher's data. Thus, researchers may deceive the participants about the details of the study. In all cases of deception, however, the psychologist must ensure that the deception will not harm the participants and that the participants will be *debriefed* (told the actual nature of the study) as soon as possible after the study is completed.

MINIMIZING BIAS

Studies of life-span development are most useful when they are conducted without bias or prejudice toward any group of people. Of special concern is bias based on gender and bias based on culture or ethnicity.

connecting with careers

Pam Reid, Educational and Development Psychologist

When she was a child, Pam Reid liked to play with chemistry sets. Reid majored in chemistry during college and wanted to become a doctor. However, when some of her friends signed up for a psychology class as an elective she also decided to take the course. She was intrigued by learning about how people think, behave, and develop—so much so that she changed her major to psychology. Reid went on to obtain her Ph.D. in psychology (American Psychological Association, 2003, p. 16).

For a number of years, Reid was professor of education and psychology at the University of Michigan, where she also was a research scientist at the Institute for Research on Women and Gender. Her main focus has been on how children and adolescents develop social skills, with a special interest in the development of African American girls (Reid & Zalk, 2001). In 2004, Reid became Provost and Executive Vice-President at Roosevelt University in Chicago, and in 2007 she became president of Saint Joseph College in Hartford, Connecticut.

Pam Reid *(center),* with students at Saint Joseph College in Hartford, Connecticut.

For more information about what educational psychologists do, see the Careers in Life-Span Development appendix.

Gender Bias For most of its existence, our society has had a strong gender bias, a preconceived notion about the abilities of women and men that prevented individuals from pursuing their own interests and achieving their potential. Gender bias also has had a less obvious effect within the field of life-span development. For example, it is not unusual for conclusions to be drawn about females' attitudes and behaviors from research conducted with males as the only participants (Helegson, 2021).

Furthermore, when researchers find gender differences, their reports sometimes magnify those differences (Denmark & others, 1988). For example, a researcher might report that 74 percent of the men in a study had high achievement expectations versus only 67 percent of the women and go on to talk about the differences in some detail. In reality, this might be a rather small difference. It also might disappear if the study were repeated, or the study might have methodological problems that don't allow such strong interpretations.

Pam Reid is a leading researcher who studies gender and ethnic bias in development. To read about Pam's interests, see the *Connecting with Careers* profile.

Cultural and Ethnic Bias There is a growing awareness that research on life-span development needs to include more people from diverse ethnic groups. Historically, people from ethnic minority groups (African American, Latinx, Asian American, and Native American) were excluded from most research in the United States and simply thought of as variations from the norm or average. If minority individuals were included in samples and their scores didn't fit the norm, they were viewed as confounds or "noise" in data and discounted (Gollnick & Chinn, 2021). Given the fact that individuals from diverse ethnic groups were excluded from research on life-span development for so long, we might reasonably conclude that people's real lives are perhaps more varied than research data have indicated in the past.

Researchers also have tended to overgeneralize about ethnic groups. **Ethnic gloss** involves using an ethnic label such as African American or Latinx in a superficial way that portrays an ethnic group as being more homogeneous than it really is (Trimble, 1988, 2021). For example, a researcher might describe a research sample like this: "The participants were 60 Latinxs." A more complete description of the Latinx group might be something like this: "The 60 Latinx participants were Mexican Americans from low-income

ethnic gloss Use of an ethnic label such as African American or Latinx in a superficial way that portrays an ethnic group as being more homogeneous than it really is.

Look at these two photographs, one of all non-Latinx White males, the other of a diverse group of females and males from different ethnic groups, including some non-Latinx White males. Consider a topic in life-span development, such as parenting, love, or cultural values. *If you were conducting research on this topic, might the results of the study be different depending on whether the participants in your study were the individuals in the photograph on the left or the right?*

(*Left*): Anthony Cassidy/The Image Bank/Getty Images; (*right*): Punchstock/Digital Vision

neighborhoods in the southwestern area of Los Angeles. Thirty-six were from homes in which Spanish is the dominant spoken language, 24 from homes in which English is the main spoken language. Thirty were born in the United States, 30 in Mexico. Twenty-eight described themselves as Mexican American, 14 as Mexican, 9 as American, 6 as Chicano, and 3 as Latinx." Ethnic gloss can cause researchers to obtain samples of ethnic groups that are not representative of the group's diversity, which can lead to overgeneralization and stereotyping.

The growing proportion of minority families in the U.S. population in approaching decades will mainly be due to the immigration of Latinx and Asian families. Researchers need to consider their acculturation level as well as the generational status of parents and children and examine how these factors influence family relationships and child outcomes (Parke, Roisman, & Rose, 2020). More attention also needs to be given to biculturalism, because some children of color identify with two or more ethnic groups (Clauss-Ehlers, Roysircar, & Hunter, 2021). And language development research needs to focus more on dual-language acquisition and how it is linked to school achievement (Diaz-Rico, 2020).

Review *Connect* Reflect

LG4 Explain how research on life-span development is conducted.

Review

- What methods do researchers use to collect data on life-span development?
- What research designs are used to study human development?
- How are cross-sectional and longitudinal research designs different?
- What are researchers' ethical responsibilities to the people they study?
- How can gender, cultural, and ethnic bias affect the outcome of a research study?

Connect

- Earlier in this chapter you read about research on age-related memory decline that revealed some potential biases based on the type of information involved and the time of day when the testing was done. How might researchers study memory decline while accounting for such possible biases?

Reflect *Your Own Personal Journey of Life*

- Imagine that you are conducting a research study on the sexual attitudes and behaviors of adolescents. What ethical safeguards should you use in conducting the study?

Introduction

1 The Life-Span Perspective

LG1 Discuss the distinctive features of a life-span perspective on development.

The Importance of Studying Life-Span Development

- Development is the pattern of change that begins at conception and continues through the life span. It includes both growth and decline.
- Studying life-span development helps prepare us to take responsibility for children, gives us insight about our own lives, and gives us knowledge about what our lives will be like as we age.

Characteristics of the Life-Span Perspective

- The life-span perspective includes the following basic concepts: development is lifelong, multidimensional, multidirectional, and plastic; its study is multidisciplinary; it is embedded in contexts; it involves growth, maintenance, and regulation; and it is a co-construction of biological, sociocultural, and individual factors.
- Three important sources of contextual influences are (1) normative age-graded influences, (2) normative history-graded influences, and (3) nonnormative life events.

Some Contemporary Concerns

- Health and well-being, parenting, education, sociocultural contexts and diversity, and social policy are all areas of contemporary concern that are closely tied to life-span development.
- Important dimensions of the sociocultural context include culture, ethnicity, socioeconomic status, and gender.
- There is increasing interest in social policy issues related to children and to older adults, as well as the importance of resiliency in development.
- Recently there has been a dramatic infusion of technology in the lives of people of all ages, and the influence of technology on development is an important contemporary issue.

2 The Nature of Development

LG2 Identify the most important processes, periods, and issues in development.

Biological, Cognitive, and Socioemotional Processes

- Three key categories of developmental processes are biological, cognitive, and socioemotional. Development is influenced by an interplay of these processes.

Periods of Development

- The life span is commonly divided into the following periods of development: prenatal, infancy, early childhood, middle and late childhood, adolescence, early adulthood, middle adulthood, and late adulthood. Attention is increasingly being directed to age differences in functioning within the late adulthood period, especially between the young old (65 through 84) and oldest old (85 and older). Also, a number of proposals have recently been made to consider the changing age range and characteristics of various age periods from emerging adulthood through late adulthood.

The Significance of Age

- An increasing number of studies have found that as adults get older they are happier.
- We often think of age only in terms of chronological age, but a full evaluation of age requires consideration of chronological, biological, psychological, and social age.

Developmental Issues

- The nature-nurture issue focuses on the extent to which development is mainly influenced by nature (biological inheritance) or nurture (experience).

- The stability-change issue focuses on the degree to which we become older renditions of our early experience or develop into someone different from who we were earlier in development. A special aspect of the stability-change issue is the extent to which development is determined by early versus later experiences.
- Developmentalists describe development as continuous (gradual, a cumulative change) or as discontinuous (abrupt, a sequence of stages).
- Most developmentalists recognize that extreme positions on the nature-nurture, stability-change, and continuity-discontinuity issues are unwise. Despite this consensus, there is still spirited debate on these issues.

3 Theories of Development

LG3 Describe the main theories of human development.

Psychoanalytic Theories

- The scientific method involves four main steps: (1) conceptualize a problem, (2) collect data, (3) analyze data, and (4) draw conclusions. Theory is often involved in conceptualizing a problem. A theory is an interrelated, coherent set of ideas that helps to explain phenomena and to make predictions. Hypotheses are specific assertions and predictions, often derived from theory, that can be tested.
- According to psychoanalytic theories, development primarily depends on the unconscious mind and is heavily couched in emotion. Freud also argued that individuals go through five psychosexual stages.
- Erikson's theory emphasizes eight psychosocial stages of development: trust versus mistrust, autonomy versus shame and doubt, initiative versus guilt, industry versus inferiority, identity versus identity confusion, intimacy versus isolation, generativity versus stagnation, and integrity versus despair.
- Contributions of psychoanalytic theories include an emphasis on a developmental framework, family relationships, and unconscious aspects of the mind. Criticisms include a lack of scientific support for psychoanalytic theories, too much emphasis on sexual underpinnings, and an image of people that is too negative.

Cognitive Theories

- Three main cognitive theories are Piaget's, Vygotsky's, and information processing. Cognitive theories emphasize thinking, reasoning, language, and other cognitive processes.
- Piaget proposed a cognitive developmental theory in which children use their cognition to adapt to their world. In Piaget's theory, children go through four cognitive stages: sensorimotor, preoperational, concrete operational, and formal operational.
- Vygotsky's sociocultural cognitive theory emphasizes how culture and social interaction guide cognitive development.
- The information-processing approach emphasizes that individuals manipulate information, monitor it, and strategize about it.
- Contributions of cognitive theories include an emphasis on the active construction of understanding and developmental changes in thinking. Criticisms include giving too little attention to individual variations and underrating the unconscious aspects of thought.

Behavioral and Social Cognitive Theories

- Two main behavioral and social cognitive theories are Skinner's operant conditioning and social cognitive theory.
- In Skinner's operant conditioning, the consequences of a behavior produce changes in the probability of the behavior's occurrence.
- In social cognitive theory, observational learning is a key aspect of life-span development. Bandura emphasizes reciprocal interactions among person/cognition, behavior, and environment.

- Contributions of the behavioral and social cognitive theories include an emphasis on scientific research, a focus on environmental factors, and recognition of the importance of person and cognitive factors in social cognitive theory. Criticisms include inadequate attention to developmental changes, too much emphasis on environmental determinants, and (in Skinner's behaviorism) too little attention to cognition.

Ethological Theory

- Ethology stresses that behavior is strongly influenced by biology, is tied to evolution, and is characterized by critical or sensitive periods.
- Contributions of ethological theory include its focus on the biological and evolutionary basis of development. Criticisms include inflexibility regarding the concepts of critical and sensitive periods.

Ecological Theory

- Ecological theory emphasizes environmental contexts. Bronfenbrenner's environmental systems view of development proposes five environmental systems: microsystem, mesosystem, exosystem, macrosystem, and chronosystem.
- Contributions of the theory include a systematic examination of micro and macro dimensions of environmental systems and consideration of sociohistorical influences. Criticisms include inadequate attention to biological factors, as well as a lack of emphasis on cognitive factors.

An Eclectic Theoretical Orientation

- An eclectic theoretical orientation does not follow any one theoretical approach but rather selects from each theory whatever is considered the best in it.

4 Research on Life-Span Development

LG4 Explain how research on life-span development is conducted.

Methods for Collecting Data

- Methods for collecting data about life-span development include observation (in a laboratory or a naturalistic setting), survey (questionnaire) or interview, standardized test, case study, and physiological measures.

Research Designs

- Three main research designs are descriptive, correlational, and experimental. Descriptive research aims to observe and record behavior. The goal of correlational research is to describe the strength of the relationship between two or more events or characteristics. Experimental research involves conducting an experiment, which can determine cause and effect. An independent variable is the manipulated, influential, experimental factor. A dependent variable is a factor that can change in an experiment, in response to changes in the independent variable. Experiments can involve one or more experimental groups and control groups. In random assignment, researchers assign participants to experimental and control groups by chance.

Time Span of Research

- When researchers decide about the time span of their research, they can conduct cross-sectional or longitudinal studies. Life-span researchers are especially concerned about cohort effects.

Conducting Ethical Research

- Researchers' ethical responsibilities include seeking participants' informed consent, ensuring their confidentiality, debriefing them about the purpose and potential personal consequences of participating, and avoiding unnecessary deception of participants.

Minimizing Bias

- Researchers need to guard against gender, cultural, and ethnic bias in research. Every effort should be made to make research equitable for both females and males.
- Individuals from varied ethnic backgrounds need to be included as participants in life-span research, and overgeneralization about diverse members within a group must be avoided.

appendix

Careers in Life-Span Development

The field of life-span development offers an amazing breadth of careers that can provide extremely satisfying work. College and university professors teach courses in many areas of life-span development. Teachers impart knowledge, understanding, and skills to children and adolescents. Counselors, clinical psychologists, nurses, and physicians help people of different ages to cope more effectively with their lives and improve their well-being.

These and many other careers related to life-span development offer many rewards. By working in the field of life-span development, you can help people to improve their lives, understand yourself and others better, possibly advance the state of knowledge in the field, and have an enjoyable time while you are doing these things. Many careers in life-span development pay reasonably well. For example, psychologists earn well above the median salary in the United States.

If you are considering a career in life-span development, would you prefer to work with infants? children? adolescents? older adults? As you go through this term, try to spend some time with people of different ages. Observe their behavior. Talk with them about their lives. Think about whether you would like to work with people of this age on a daily basis.

In addition, to find out about careers in life-span development you might talk with people who work in various jobs. For example, if you have some interest in becoming a school counselor, call a school, ask to speak with a counselor, and set up an appointment to discuss the counselor's career and work. If you have an interest in becoming a nurse, call the nursing department at a hospital and set up an appointment to speak with the nursing coordinator about a nursing career.

Another way to explore careers in life-span development is to work in a related job while you are in college. Many colleges and universities offer internships or other work experiences for students who major in specific fields. Course credit or pay is given for some of these jobs. Take advantage of these opportunities. They can help you decide if this is the right career for you, and they can help you get into graduate school if you choose to acquire additional education after earning your undergraduate degree.

An advanced degree is not absolutely necessary for some careers in life-span development, but usually you can considerably expand your opportunities (and income) by obtaining a graduate degree. If you think you might want to go to graduate school, talk with one or more professors about your interests, maintain a high grade-point average, take appropriate courses, and realize that you likely will need to take the Graduate Record Examination at some point.

We will profile a number of careers in four areas: education/research; clinical/counseling; medical/nursing/physical development; and families/relationships. These are not the only career options in life-span development, but the profiles should give you an idea of the range of opportunities available. For each career, we describe the work and address the amount of education required and the nature of the training. We have provided chapter titles after some entries telling you where to find *Connecting with Careers*, the career profiles of people who hold some of these positions.

Education/Research

Numerous careers in life-span development involve education or research. The opportunities range from college professor to preschool teacher to school psychologist.

College/University Professor

Professors teach courses in life-span development at many types of institutions, including research universities with master's or Ph.D. programs in life-span development, four-year colleges with no graduate programs, and community colleges. The courses in life-span development are offered in many different programs and schools, including psychology, education, nursing, child and family studies, social work, and medicine. In addition to teaching at the undergraduate or graduate level (or both), professors may conduct research, advise students or direct their research, and serve on college or university committees. Research is part of a professor's job description at most universities with master's and Ph.D. programs, but some college professors do not conduct research and focus instead on teaching.

Teaching life-span development at a college or university almost always requires a Ph.D. or master's degree. Obtaining a Ph.D. usually takes four to six years of graduate work; a master's degree requires approximately two years. The training involves taking graduate courses, learning to conduct research, and attending and presenting papers at professional meetings. Many graduate students work as teaching or research assistants for professors in an apprenticeship relationship that helps them to become competent teachers and researchers. **Read the profiles of professors in "Gender and Sexuality" and "Peers and the Sociocultural World."**

Researcher

Some individuals in the field of life-span development work in research positions. They might work for a university, a government agency such as the National Institute of Mental Health, or private industry. They generate research ideas, plan studies, carry out the research, and usually attempt to publish the research results in a scientific journal. A researcher often works in collaboration with other researchers. One researcher might spend much of his or her time in a laboratory; another researcher might work in the field, such as in schools, hospitals, and so on. Most researchers in life-span development have either a master's degree or a Ph.D.

Elementary or Secondary School Teacher

Elementary and secondary school teachers teach one or more subject areas, preparing the curriculum, giving tests, assigning grades, monitoring students' progress, conducting parent-teacher conferences, and attending workshops. Becoming an elementary or secondary school teacher requires a minimum of an undergraduate degree. The training involves taking a wide range of courses with a major or concentration in education as well as completing supervised practice teaching.

Exceptional Children (Special Education) Teacher

Teachers of exceptional children spend concentrated time with children who have a disability such as ADHD, intellectual disability, or cerebral palsy, or with children who are gifted. Usually some of their work occurs outside of the students' regular classroom and some of it inside the students' regular classroom. A teacher of exceptional children works closely with the student's regular classroom teacher and parents to create the best educational program for the student. Teachers of exceptional children often continue their education after obtaining their undergraduate degree and attain a master's degree.

Early Childhood Educator

Early childhood educators work on college faculties and usually teach in community colleges that award an associate degree in early childhood education. They have a minimum of a master's degree

in their field. In graduate school, they take courses in early childhood education and receive supervisory training in child-care or early childhood programs.

Preschool/Kindergarten Teacher

Preschool teachers teach mainly 4-year-old children, and kindergarten teachers primarily teach 5-year-old children. They usually have an undergraduate degree in education, specializing in early childhood education. State certification to become a preschool or kindergarten teacher usually is required.

Family and Consumer Science Educator

Family and consumer science educators may specialize in early childhood education or instruct middle and high school students about such matters as nutrition, interpersonal relationships, human sexuality, parenting, and human development. Hundreds of colleges and universities throughout the United States offer two- and four-year degree programs in family and consumer science. These programs usually require an internship. Additional education courses may be needed to obtain a teaching certificate. Some family and consumer educators go on to graduate school for further training, which provides a background for possible jobs in college teaching or research. **Read a profile of a family and consumer science educator in "Gender and Sexuality."**

Educational Psychologist

Educational psychologists most often teach in a college or university and conduct research in various areas of educational psychology such as learning, motivation, classroom management, and assessment. They help train students for positions in educational psychology, school psychology, and teaching. Most educational psychologists have a doctorate in education, which takes four to six years of graduate work. **Read a profile of an educational psychologist in "Introduction."**

School Psychologist

School psychologists focus on improving the psychological and intellectual well-being of elementary, middle/junior, and high school students. They give psychological tests, interview students and their parents, consult with teachers, and may provide counseling to students and their families. They may work in a centralized office in a school district or in one or more schools.

School psychologists usually have a master's or doctoral degree in school psychology. In graduate school, they take courses in counseling, assessment, learning, and other areas of education and psychology.

Gerontologist

Gerontologists usually work in research in some branch of the federal or state government. They specialize in the study of aging with a particular focus on government programs for older adults, social policy, and delivery of services to older adults. In their research, gerontologists define problems to be studied, collect data, interpret the results, and make recommendations for social policy. Most gerontologists have a master's or doctoral degree and have taken a concentration of coursework in adult development and aging.

Clinical/Counseling

A wide variety of clinical and counseling jobs are linked with life-span development. These range from child clinical psychologist to adolescent drug counselor to geriatric psychiatrist.

Clinical Psychologist

Clinical psychologists seek to help people with psychological problems. They work in a variety of settings, including colleges and universities, clinics, medical schools, and private practice. Some clinical psychologists only conduct psychotherapy; others do psychological assessment and psychotherapy; some also do research. Clinical psychologists may specialize in a particular age group, such as children (child clinical psychologist) or older adults (geropsychologist).

Clinical psychologists have either a Ph.D. (which involves clinical and research training) or a Psy.D. degree (which only involves clinical training). This graduate training usually takes five to seven years and includes courses in clinical psychology and a one-year supervised internship in an accredited setting toward the end of the training. Many geropsychologists pursue a year or two of postdoctoral training. Most states require clinical psychologists to pass a test in order to become licensed in the state and to call themselves clinical psychologists.

Psychiatrist

Psychiatrists obtain a medical degree and then do a residency in psychiatry. Medical school takes approximately four years and the psychiatry residency another three to four years. Unlike most psychologists (who do not go to medical school), psychiatrists can administer drugs to clients. (Recently, several states gave clinical psychologists the right to prescribe drugs.)

Like clinical psychologists, psychiatrists might specialize in working with children (child psychiatry) or with older adults (geriatric psychiatry). Psychiatrists might work in medical schools in teaching and research roles, in a medical clinic or hospital, or in private practice. In addition to administering drugs to help improve the lives of people with psychological problems, psychiatrists also may conduct psychotherapy. **Read a profile of a child psychiatrist in "Schools, Achievement, and Work."**

Counseling Psychologist

Counseling psychologists work in the same settings as clinical psychologists and may do psychotherapy, teach, or conduct research. Many counseling psychologists do not do therapy with individuals who have severe mental disorders, such as schizophrenia.

Counseling psychologists go through much the same training as clinical psychologists, although in a graduate program in counseling rather than clinical psychology. Counseling psychologists have either a master's degree or a doctoral degree. They also must go through a licensing procedure. One type of master's degree in counseling leads to the designation of licensed professional counselor.

School Counselor

School counselors help students cope with adjustment problems, identify their abilities and interests, develop academic plans, and explore career options. The focus of the job depends on the age of the children. High school counselors advise students about vocational and technical training and admissions requirements for college, as well as about taking entrance exams, applying for financial aid, and choosing a major. Elementary school counselors mainly counsel students about social and personal problems. They may observe children in the classroom and at play as part of their work. School counselors may work with students individually, in small groups, or even in a classroom. They often consult with parents, teachers, and school administrators when trying to help students. School counselors usually have a master's degree in counseling. **Read a profile of a high school counselor in "The Self, Identity, and Personality."**

Career Counselor

Career counselors help individuals to identify their best career options and guide them in applying for jobs. They may work in private industry or at a college or university. They usually interview individuals and give them vocational and/or psychological tests to identify appropriate careers that fit their interests and abilities. Sometimes they help individuals to create résumés or conduct mock interviews to help them feel comfortable in a job interview. They might arrange and promote job fairs or other recruiting events to help individuals obtain jobs.

Rehabilitation Counselor

Rehabilitation counselors work with individuals to identify career options, develop adjustment and coping skills to maximize independence, and resolve problems created by a disability. A master's degree in rehabilitation counseling or guidance or counseling psychology is generally considered the minimum educational requirement.

Social Worker

Many social workers are involved in helping people with social or economic problems. They may investigate, evaluate, and attempt to rectify

reported cases of abuse, neglect, endangerment, or domestic disputes. They may intervene in families and provide counseling and referral services to individuals and families. Some social workers specialize in a certain area. For example, a medical social worker might coordinate support services to people with a long-term disability; family-care social workers often work with families with children or an older adult who needs support services. Social workers often work for publicly funded agencies at the city, state, or national level, although increasingly they work in the private sector in areas such as drug rehabilitation and family counseling.

Social workers have a minimum of an undergraduate degree from a school of social work that includes coursework in sociology and psychology. Some social workers also have a master's or doctoral degree. For example, medical social workers have a master's degree in social work (M.S.W.) and complete graduate coursework and supervised clinical experiences in medical settings.

Drug Counselor

Drug counselors provide counseling to individuals with drug-abuse problems. Some drug counselors specialize in working with adolescents or older adults. They may work on an individual basis with a substance abuser or conduct group therapy. They may work in private practice, with a state or federal government agency, for a company, or in a hospital.

At a minimum, drug counselors complete an associate's or certificate program. Many have an undergraduate degree in substance-abuse counseling, and some have master's and doctoral degrees. Most states provide a certification procedure for obtaining a license to practice drug counseling.

Medical/Nursing/Physical Development

This third main area of careers in life-span development includes a wide range of choices in the medical and nursing areas, as well as jobs pertaining to improving some aspect of a person's physical development.

Obstetrician/Gynecologist

An obstetrician/gynecologist prescribes prenatal and postnatal care, performs deliveries in maternity cases, and treats diseases and injuries of the female reproductive system. Becoming an obstetrician/gynecologist requires a medical degree plus three to five years of residency in obstetrics/gynecology. Obstetricians may work in private practice, a medical clinic, a hospital, or a medical school.

Pediatrician

A pediatrician monitors infants' and children's health, works to prevent disease or injury, helps children attain optimal health, and treats children with health problems. Pediatricians have earned a medical degree and completed a three- to five-year residency in pediatrics.

Pediatricians may work in private practice or at a medical clinic, a hospital, or a medical school. Many pediatricians on the faculty of medical schools also teach and conduct research on children's health and diseases.

Geriatric Physician

Geriatric physicians diagnose medical problems of older adults, evaluate treatment options, and make recommendations for nursing care or other arrangements. They have a medical degree and specialize in geriatric medicine by doing a three- to five-year residency. Like other doctors, geriatric physicians may work in private practice or at a medical clinic, a hospital, or a medical school. Those in medical school settings may not only treat older adults but also teach future physicians and conduct research.

Neonatal Nurse

Neonatal nurses deliver care to newborn infants. They may work with infants born under normal circumstances or premature and critically ill neonates. A minimum of an undergraduate degree in nursing with a specialization in the newborn is required. This training involves coursework in nursing and the biological sciences, as well as supervised clinical experiences.

Nurse-Midwife

A nurse-midwife formulates and provides comprehensive care to expectant mothers as they prepare to give birth, guides them through the birth process, and cares for them after the birth. The nurse-midwife also may provide care to the newborn, counsel parents on the infant's development and parenting, and provide guidance about health practices. Becoming a nurse-midwife generally requires an undergraduate degree from a school of nursing. A nurse-midwife most often works in a hospital setting. **Read a profile of a perinatal nurse in "Biological Beginnings."**

Pediatric Nurse

Pediatric nurses monitor infants' and children's health, work to prevent disease or injury, and help children attain optimal health. They may work in hospitals, schools of nursing, or with pediatricians in private practice or at a medical clinic.

Pediatric nurses have a degree in nursing that takes two to five years to complete. They take courses in biological sciences, nursing care, and pediatrics, usually in a school of nursing. They also undergo supervised clinical experiences in medical settings. Some pediatric nurses go on to earn a master's or doctoral degree in pediatric nursing. **Read a profile of a pediatric nurse in "Health."**

Geriatric Nurse

Geriatric nurses seek to prevent or intervene in the chronic or acute health problems of older adults. They may work in hospitals, nursing homes, schools of nursing, or with geriatric medical specialists or psychiatrists in a medical clinic or in private practice. Like pediatric nurses, geriatric nurses take courses in a school of nursing and obtain a degree in nursing, which takes from two to five years. They complete courses in biological sciences, nursing care, and mental health as well as supervised clinical training in geriatric settings. They also may obtain a master's or doctoral degree in their specialty. **Read a profile of a geriatric nurse in "Physical Development and Biological Aging."**

Physical Therapist

Physical therapists work with individuals who have a physical problem due to disease or injury to help them function as competently as possible. They may consult with other professionals and coordinate services for the individual. Many physical therapists work with people of all ages, although some specialize in working with a specific age group, such as children or older adults.

Physical therapists usually have an undergraduate degree in physical therapy and are licensed by a state. They take courses and undergo supervised training in physical therapy.

Occupational Therapist

Occupational therapists initiate the evaluation of clients with various impairments and manage their treatment. They help people regain, develop, and build skills that are important for independent functioning, health, well-being, security, and happiness. An "Occupational Therapist Registered" (OTR) must have a master's and/or doctoral degree with education ranging from two to six years. Training includes occupational therapy courses in a specialized program. National certification is required, and licensing/registration is required in some states.

Therapeutic/Recreation Therapist

Therapeutic/recreation therapists maintain or improve the quality of life for people with special needs through intervention, leisure education, and recreation. They work in hospitals, rehabilitation centers, local government agencies, at-risk youth programs, and other settings. Becoming a therapeutic/recreation therapist requires an undergraduate degree with coursework in leisure studies and a concentration in therapeutic recreation. National certification is usually required. Coursework in anatomy, special education, and psychology is beneficial.

Audiologist

Audiologists assess and identify the presence and severity of hearing loss, as well as problems in balance. They may work in a medical clinic, with a physician in private practice, in a hospital, or in a medical school.

An audiologist completes coursework and supervised training to earn a minimum of an

undergraduate degree in hearing science. Some audiologists also go on to obtain a master's or doctoral degree.

Speech Therapist

Speech therapists identify, assess, and treat speech and language problems. They may work with physicians, psychologists, social workers, and other health care professionals in a team approach to help individuals with physical or psychological problems that involve speech and language. Some speech therapists specialize in working with individuals of a particular age or people with a particular type of speech disorder. Speech therapists have a minimum of an undergraduate degree in speech and hearing science or in a type of communication disorder. They may work in private practice, hospitals and medical schools, and government agencies. **Read a profile of a speech therapist in "Language Development."**

Genetic Counselor

Genetic counselors identify and counsel families at risk for genetic disorders. They work as members of a health care team, providing information and support to families who have members who have genetic defects or disorders or are at risk for a variety of inherited conditions. They also serve as educators and resource people for other health care professionals and the public. Almost half of genetic counselors work in university medical centers; one-fourth work in private hospital settings.

Genetic counselors have specialized graduate degrees and experience in medical genetics and counseling. As undergraduates, most genetic counselors majored in disciplines such as biology, genetics, psychology, nursing, public health, or social work. **Read a profile of a genetic counselor in "Biological Beginnings."**

Families/Relationships

A number of careers and jobs related to life-span development focus on working with families and addressing relationship problems. These range from home health aide to marriage and family therapist.

Home Health Aide

A home health aide provides services to older adults in the older adults' homes, helping them with basic self-care tasks. No higher education is required for this position. There is brief training by an agency.

Child Welfare Worker

Child protective services in each state employ child welfare workers. They protect children's rights, evaluate any maltreatment, and may have children removed from their homes if necessary. A child social worker has a minimum of an undergraduate degree in social work.

Child Life Specialist

Child life specialists work with children and their families when the child needs to be hospitalized. They monitor the child's activities, seek to reduce the child's stress, and help the child to cope and to enjoy the hospital experience as much as possible. Child life specialists may provide parent education and develop individualized treatment plans based on an assessment of the child's development, temperament, medical plan, and available social supports. Child life specialists have an undergraduate degree. They have taken courses in child development and education and usually completed additional courses in a child life program.

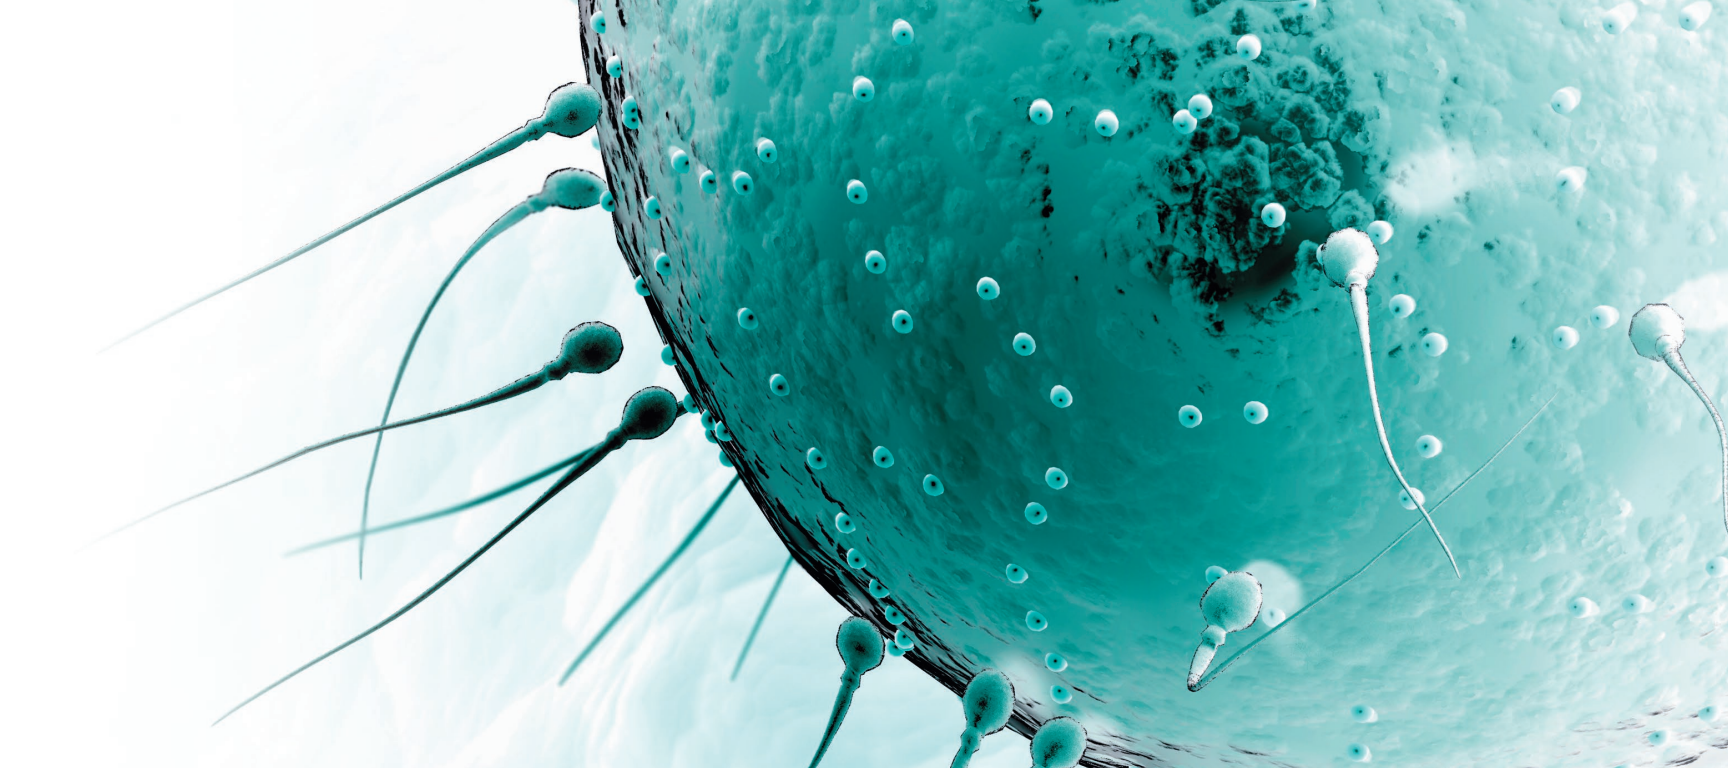
Marriage and Family Therapist

Marriage and family therapists work on the principle that many individuals who have psychological problems benefit when psychotherapy is provided in the context of a marital or family relationship. Marriage and family therapists may provide marital therapy, couple therapy to individuals in a relationship who are not married, and family therapy to two or more members of a family.

Marriage and family therapists have a master's or a doctoral degree. They complete a training program in graduate school similar to a clinical psychologist's but with a focus on marital and family relationships. In most states, it is necessary to go through a licensing procedure to practice marital and family therapy. **Read a profile of a marriage and family therapist in "Families, Lifestyles, and Parenting."**

Further Careers

Knowledge of developmental psychology can prepare you for these careers and many others. The *Connecting with Careers* profiles highlight additional careers, including an infant assessment specialist, child care director, toy designer, health psychologist, teacher of English language learners, college/career counselor, parent educator, pastoral counselor, and home hospice nurse. *What other careers can you think of that require knowledge of human development?*



MedicalRF.com/Getty Images

section two

Biological Processes, Physical Development, and Health

Babies are such a nice way to start people.

–Don Herold
American Writer, 20th Century

The rhythm and meaning of life involve biological foundations. How, from so simple a beginning, can endless forms develop and grow and mature? What was this organism, what is it, and what will it be? In Section 2, you will read and study four chapters: "Biological Beginnings," "Physical Development and Biological Aging," "Health," and "Motor, Sensory, and Perceptual Development."

chapter 2

BIOLOGICAL BEGINNINGS

chapter **outline**

1 The Evolutionary Perspective

Learning Goal 1 Discuss the evolutionary perspective on life-span development.

Natural Selection and Adaptive Behavior
Evolutionary Psychology

2 Genetic Foundations of Development

Learning Goal 2 Describe what genes are and how they influence human development.

The Collaborative Gene
Genes and Chromosomes
Genetic Principles
Chromosomal and Gene-Linked Abnormalities

3 Heredity and Environment Interaction: The Nature-Nurture Debate

Learning Goal 3 Explain some of the ways that heredity and environment interact to produce individual differences in development.

Behavior Genetics
Heredity-Environment Correlations
The Epigenetic View and Gene × Environment (G × E) Interaction
Conclusions About Heredity-Environment Interaction

4 Prenatal Development

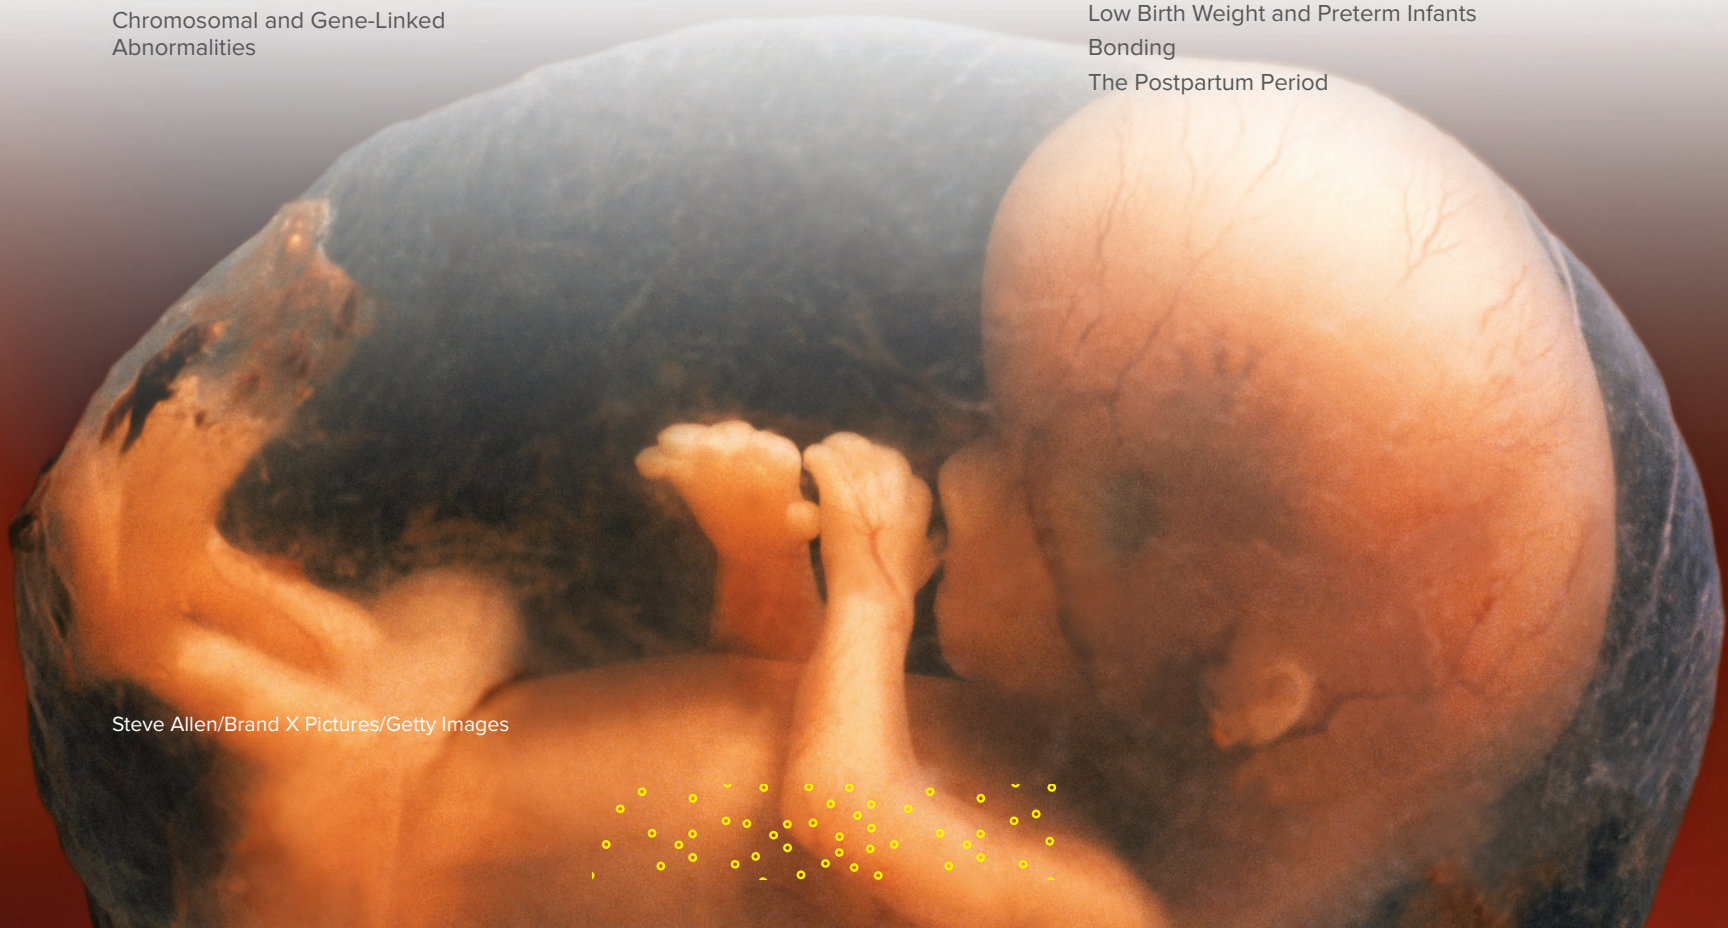
Learning Goal 4 Characterize the course of prenatal development and its hazards.

The Course of Prenatal Development
Prenatal Diagnostic Tests
Hazards to Prenatal Development
Prenatal Care

5 Birth and the Postpartum Period

Learning Goal 5 Summarize how birth takes place and describe the nature of the postpartum period.

The Birth Process
The Transition from Fetus to Newborn
Low Birth Weight and Preterm Infants
Bonding
The Postpartum Period



Steve Allen/Brand X Pictures/Getty Images

preview

Organisms are not like billiard balls, moved by simple external forces to predictable positions on life's table. Environmental experiences and biological foundations work together to make us who we are. In this chapter, we explore life's biological beginnings and experiences, charting growth from conception through the prenatal period and examining the birth process itself. We will begin our exploration of biological foundations by considering possible evolutionary influences.

1 The Evolutionary Perspective

LG1 Discuss the evolutionary perspective on life-span development.

Natural Selection and Adaptive Behavior

Evolutionary Psychology

From the perspective of evolutionary time, humans are relative newcomers to Earth. As our earliest ancestors left the forest to feed on the savannahs and then to form hunting societies on the open plains, their minds and behaviors changed, and humans eventually became the dominant species on Earth. How did this evolution come about?

How does the attachment of this Vietnamese baby to its mother reflect the evolutionary process of adaptive behavior?
Michele Burgess/Alamy Stock Photo

NATURAL SELECTION AND ADAPTIVE BEHAVIOR

Charles Darwin (1859) described *natural selection* as the evolutionary process by which those individuals of a species that are best adapted to their environment are the ones that are most likely to survive and reproduce. He reasoned that an intense, constant struggle for food, water, and resources must occur among the young of each generation, because many of them do not survive. Those that do survive and reproduce pass on their characteristics to the next generation (Cowan & Smith, 2021). Darwin concluded that these survivors are better adapted to their world than are the nonsurvivors. The best-adapted individuals survive and leave the most offspring. Over the course of many generations, organisms with the characteristics needed for survival make up an increased percentage of the population (Hoefnagels, 2021).

EVOLUTIONARY PSYCHOLOGY

Although Darwin introduced the theory of evolution by natural selection in 1859, his ideas have only recently become a popular framework for explaining behavior (Lewis, Al-Shawaf, & Buss, 2021). Psychology's newest approach, **evolutionary psychology,** emphasizes the importance of adaptation, reproduction, and "survival of the fittest" in shaping behavior. ("Fit" in this sense refers to the ability to bear offspring that survive long enough to bear offspring of their own.) In this view, natural selection favors behaviors that increase reproductive success—that is, the ability to pass genes to the next generation (Zagaria, Ando, & Zennaro, 2020).

David Buss (2012, 2019) argues that just as evolution shapes our physical features, such as body shape and height, it also pervasively influences how we make decisions, how aggressive we are, our fears, and our mating patterns. For example, assume that our ancestors were hunters and gatherers on the plains and that men did most of the hunting and women stayed close to home, gathering seeds and plants for food. If you had to walk some distance from your home to track and slay a fleeing animal, you would need not only certain physical traits but also the ability to perform certain types of spatial thinking. Men with these traits would be more likely than men without them to survive, to bring home lots of food, and to be considered attractive mates—and thus to reproduce and potentially pass on these characteristics to their children. In other words, if these assumptions were correct, these traits would provide a reproductive advantage for males, and over many generations, men with good spatial thinking skills

evolutionary psychology A branch of psychology that emphasizes the importance of adaptation, reproduction, and "survival of the fittest" in shaping behavior.

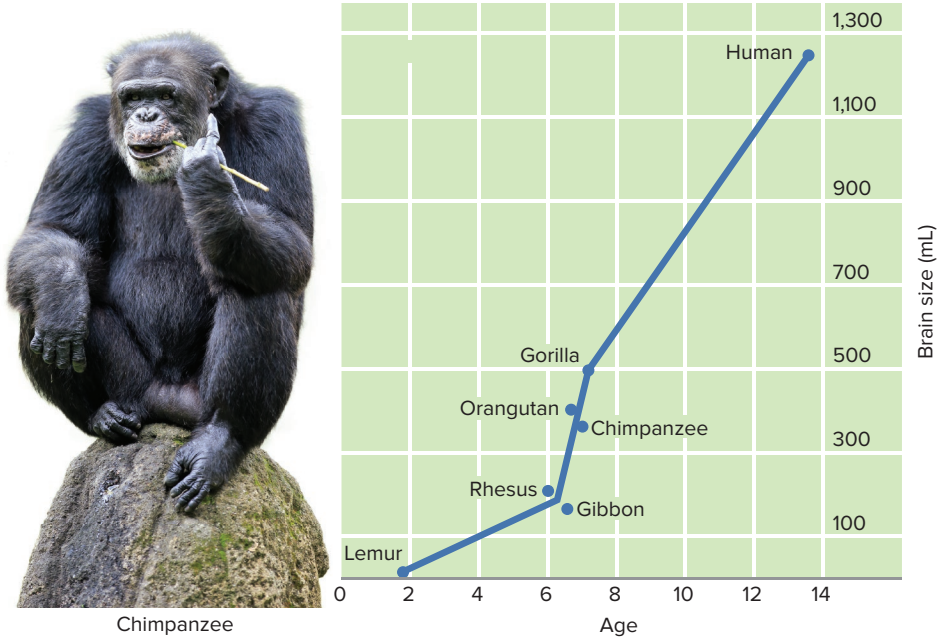


FIGURE 1

THE BRAIN SIZES OF VARIOUS PRIMATES AND HUMANS IN RELATION TO THE LENGTH OF THE CHILDHOOD PERIOD. Compared with other primates, humans have both a larger brain and a longer childhood period. *What conclusions can you draw from the relationship indicated by this graph?*

Children in all cultures are interested in the tools that adults in their cultures use. Shown here is a young child using a machete to cut wood near the Ankgor temples in Cambodia. *Might the child's behavior be evolutionary-based or be due to both biological and environmental conditions?*

Carol Adam/Moment Editorial/Getty Images

might become more numerous in the population. Critics point out that this scenario might or might not have actually happened.

Evolutionary Developmental Psychology There is growing interest in using the concepts of evolutionary psychology to understand human development (Ko & others, 2020). Following are some ideas proposed by evolutionary developmental psychologists (Bjorklund & Pellegrini, 2002).

One important concept is that an extended childhood period might have evolved because humans require time to develop a large brain and learn the complexity of human societies. Humans take longer to become reproductively mature than any other mammal (see Figure 1). During this extended childhood period, they develop a large brain and have the experiences needed to become competent adults in a complex society.

Evolved characteristics are not always adaptive in contemporary society. Some behaviors that were adaptive for our prehistoric ancestors may not serve us well today. For example, the food-scarce environment of our ancestors likely led to humans' propensity to gorge when food is available and to crave high-caloric foods, a trait that might lead to an epidemic of obesity when food is plentiful.

Evolution and Life-Span Development In evolutionary theory, what matters is that individuals live long enough to reproduce and pass on their characteristics (Urry & others, 2021). So why do humans live so long after their reproductive capacity has ended? Perhaps evolution favored longevity because having older people around improves the survival rates of babies. Possibly an evolutionary advantage came from having grandparents alive to care for the young while parents were out hunting and gathering food.

According to life-span developmentalist Paul Baltes (2003), the benefits conferred by evolutionary selection decrease with age. Natural selection has not weeded out many harmful conditions and nonadaptive characteristics that appear among older adults. Why? Natural selection operates primarily on characteristics that are tied to reproductive fitness, which

developmental **connection**

Life-Span Perspective

Baltes described eight main characteristics of the life-span perspective. Connect to "Introduction."

extends through the earlier part of adulthood. Thus, says Baltes, selection primarily operates during the first half of life.

As an example, consider Alzheimer disease, an irreversible brain disorder characterized by gradual deterioration (Lilford & Hughes, 2021). This disease typically does not appear until age 70 or later. If it were a disease that struck 20-year-olds, perhaps natural selection would have eliminated it eons ago.

Thus, unaided by evolutionary pressures against nonadaptive conditions, we suffer the aches, pains, and infirmities of aging. And, as the benefits of evolutionary selection decrease with age, argues Baltes, the need for culture increases (see Figure 2). That is, as older adults weaken biologically, they need culture-based resources such as cognitive skills, literacy, medical technology, and social support. For example, older adults may need help and training from other people to maintain their cognitive skills (Small, 2020).

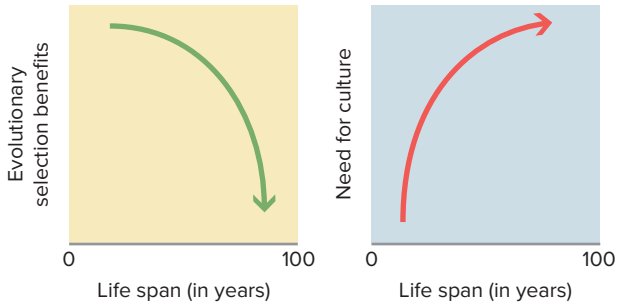

FIGURE 2

BALTES' VIEW OF EVOLUTION AND CULTURE ACROSS THE LIFE SPAN. Benefits derived from evolutionary selection decrease as we age, whereas the need for culture increases with age.

Evaluating Evolutionary Psychology Evolutionary psychology has its critics (Henrich & Muthukrishna, 2021). Common criticisms are that much of evolutionary psychology cannot be tested scientifically and that it relies mainly on *post hoc* (after the fact) explanations. Another criticism was offered by Albert Bandura (1998), the leading architect of social cognitive theory. He acknowledges the influence of evolution on human adaptation but rejects what he calls "one-sided evolutionism," which views social behavior as strictly the product of evolved biology. An alternative is a bidirectional view, in which environmental and biological conditions influence each other. In this view, evolutionary pressures created changes in biological structures that allowed the use of tools, which enabled our ancestors to manipulate the environment, constructing new environmental conditions. In turn, environmental innovations produced new selection pressures that led to the evolution of specialized biological systems for consciousness, thought, and language.

In other words, evolution has given us body structures and biological potentialities, but it does not dictate behavior. People have used their biological capacities to produce diverse cultures—aggressive and peaceful; egalitarian and autocratic.

The "big picture" idea of natural selection leading to the development of human traits and behaviors is difficult to refute or test because evolution occurs on a time scale that does not lend itself to empirical study. Indeed, as with evolution, it is very difficult to offer direct proof of an argument to support evolutionary psychology. Thus, studying specific genes in humans and other species—and their links to traits and behaviors—may be the best approach for testing ideas coming out of the evolutionary psychology perspective.

Review *Connect* Reflect

LG1 Discuss the evolutionary perspective on life-span development.

Review

- How can natural selection and adaptive behavior be defined?
- What is evolutionary psychology? What basic ideas about human development are proposed by evolutionary psychologists? How might evolutionary influences have different effects at different points in the life span? How can evolutionary psychology be evaluated?

Connect

- In the section on ethological theory in the "Introduction," the concept of a critical time period is explored. How does this concept relate to what you learned about older adults and aging in this section?

2 Genetic Foundations of Development

LG2 Describe what genes are and how they influence human development.

The Collaborative Gene | Genes and Chromosomes | Genetic Principles | Chromosomal and Gene-Linked Abnormalities

Genetic influences on behavior evolved over time and across many species. Our many traits and characteristics that are genetically influenced have a long evolutionary history that is retained in our DNA (Chess, 2021). In other words, our DNA is not just inherited from our parents; it's also what we've inherited as a species from the species that were our ancestors. Let's take a closer look at DNA and its role in human development.

How are characteristics that suit a species for survival transmitted from one generation to the next? Darwin could not answer this question because genes and the principles of genetics had not yet been discovered. Each of us carries a "genetic code" that we inherited from our parents. Because a fertilized egg carries this human code, a fertilized human egg cannot grow into an egret, eagle, or elephant.

THE COLLABORATIVE GENE

Each of us began life as a single cell weighing about one twenty-millionth of an ounce! This tiny piece of matter housed our entire genetic code—information that helps us grow from that single cell to a person made of trillions of cells, each containing a replica of the original code (Lewis, 2021). That code is carried by our genes. What are genes and what do they do? For the answer, we need to look into our cells.

The nucleus of each human cell contains **chromosomes,** which are threadlike structures made up of deoxyribonucleic acid, or DNA. **DNA** is a complex molecule that has a double helix shape, like a spiral staircase, and it contains genetic information. **Genes,** the units of hereditary information, are short segments of DNA, as you can see in Figure 3. They help cells to reproduce themselves and to assemble proteins. Proteins, in turn, are the building blocks of cells as well as the regulators that direct the body's processes (Willey & Sandman, 2021).

chromosomes Threadlike structures made up of deoxyribonucleic acid, or DNA.

DNA A complex molecule that has a double helix shape and contains genetic information.

genes Units of hereditary information composed of DNA. Genes help cells to reproduce themselves and assemble proteins that direct body processes.

Each gene has its own location, its own designated place on a particular chromosome (Brooker, 2021). Today, there is a great deal of enthusiasm about efforts to discover the specific locations of genes that are linked to certain functions and developmental outcomes (Brooker & others, 2021). An important step in this direction was accomplished in 2003 when the

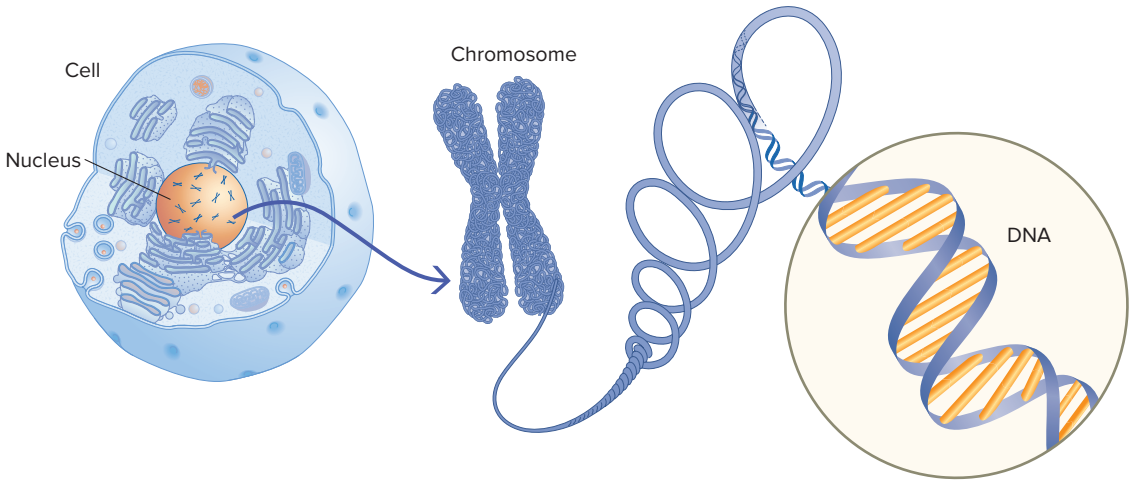

FIGURE 3

CELLS, CHROMOSOMES, DNA, AND GENES. (*Left*) The body contains trillions of cells. Each cell contains a central structure, the nucleus. (*Middle*) Chromosomes are threadlike structures located in the nucleus of the cell. Chromosomes are composed of DNA. (*Right*) DNA has the structure of a spiral staircase. A gene is a segment of DNA.

Human Genome Project completed a preliminary map of the human *genome*—the complete set of developmental information for creating proteins that initiate the making of a human organism. Among the major approaches to gene identification and discovery that are being used today are the genome-wide association method and linkage analysis.

Completion of the Human Genome Project has led to use of the *genome-wide association method* to identify genetic variations linked to a particular disorder (Lewis, 2021). To conduct a genome-wide association study, researchers obtain DNA from individuals who have the disease and others who don't have it. Then, each participant's complete set of DNA, or genome, is purified from the blood or cells and scanned on machines to determine markers of genetic variation. If the genetic variations occur more frequently in people who have the disease, the variations point to the region in the human genome where the disease-causing problem exists. Genome-wide association studies have recently been conducted for cancer (Emad & others, 2020), obesity (Warner & others, 2021), cardiovascular disease (Villar & others, 2020), depression (Wu & others, 2021), suicide (Levey & others, 2019), autism (Searles Quick, Wang, & State, 2021), attention deficit hyperactivity disorder (Verhoef & others, 2019), and Alzheimer disease (Serrano-Pozo, Das, & Hyman, 2021).

Linkage analysis, in which the goal is to discover the location of one or more genes in relation to a marker gene (whose position is already known), is often used in the search for disease genes (Huang & others, 2020). Genes transmitted to offspring tend to be close to each other, so the gene(s) involved in the disease are usually located near the marker gene. Gene linkage studies are now being conducted on a wide variety of disorders, including cardiovascular disease (Dib & others, 2021), cancer (Wang & others, 2021), attention deficit hyperactivity disorder (Bonvacini & others, 2020), depression (Vereczkei & others, 2019), bipolar disorder (Umehara & others, 2021), suicide (Sokolowski & Wasserman, 2020), posttraumatic stress disorder (van der Merwe & others, 2019), glaucoma (Trivli & others, 2020), and Alzheimer disease (Tang & others, 2020).

One of the big surprises of the Human Genome Project was a report indicating that humans have only about 30,000 genes (U.S. Department of Energy, 2001). In subsequent analyses, the number of human genes was revised downward to approximately 20,500 (Ensembl Human, 2008; Flicek & others, 2013). However, recently the humane gene figure was raised to 21,306 (Salzberg & others, 2018). Scientists had thought that humans had as many as 100,000 or more genes. They had also maintained that each gene programmed just one protein. In fact, because humans appear to have far more proteins than they have genes, there cannot be a one-to-one correspondence between genes and proteins (Commoner, 2002). Each gene is not translated, in automaton-like fashion, into one and only one protein. A gene does not act independently, as developmental psychologist David Moore (2001) emphasized by titling his book *The Dependent Gene*.

Rather than being a group of independent genes, the human genome consists of many genes that collaborate both with each other and with nongenetic factors inside and outside the body. The collaboration operates at many points. For example, the cellular machinery mixes, matches, and links small pieces of DNA to reproduce the genes, and that machinery is influenced by what is going on around it (Chess, 2021; Moore, 2017).

Whether a gene is turned "on," working to assemble proteins, is also a matter of collaboration. The activity of genes (*genetic expression*) is affected by their environment (Gottlieb, 2007; Moore, 2017). For example, hormones that circulate in the blood make their way into the cell where they can turn genes "on" and "off." And the flow of hormones can be affected by environmental conditions such as light, day length, nutrition, and behavior. Numerous studies have shown that external events outside of the original cell and the person, as well as events inside the cell, can excite or inhibit gene expression (Gottlieb, 2007; Moore, 2017). Recent research has documented that factors such as stress, exercise, nutrition, obesity, respiration, radiation, temperature, sleep, and loneliness can influence gene expression (Brown & others, 2020; Hochberg & others, 2021; Kesaniemi & others, 2019; McGhee & Hargreaves, 2020; Shu, Swanda, & Qian, 2020; Wang, Lee, & Tian, 2019; Zimmerman & others, 2019; Vardar & others, 2021). For example, one study revealed that an increase in the concentration of stress hormones such as cortisol produced a fivefold increase in DNA damage (Flint & others, 2007). Another study found that exposure to radiation changed the rate of DNA synthesis in cells (Lee & others, 2011). And research indicates that sleep deprivation can affect gene expression in negative ways, causing increased inflammation, expression of stress-related genes, and impairment of protein functioning (Gaine, Chatterjee, & Abel, 2018).

What is inherited is DNA. Everything else is developed.

James Tanner
–British Pediatrician, 20th Century

Scientists have found that certain genes are turned on or off as a result of exercise, mainly through a process called *methylation*, in which tiny atoms attach themselves to the outside of a gene (Parry, Rulands, & Reik, 2021). This process makes the gene more or less capable of receiving and responding to biochemical signals from the body (Brooker, 2021). In this way the behavior of the gene, but not its structure, is changed. Researchers also have found that diet (Ramos-Lopez & others, 2021), stress (Gatta & others, 2021), tobacco use (Maeda & others, 2020), and sleep (Koopman-Verhoeff & others, 2020) are linked to gene expression through the process of methylation. Also, recent research indicates that methylation is involved hypertension (Amenyah & others, 2021), breast cancer (Xu & others, 2021), colorectal cancer (Alvizo-Rodriguez & others, 2020), leukemia (Kingsley & others, 2020), obesity (Gomez-Alonso & others, 2021), depression (Lapato & others, 2021), and attention deficit hyperactivity disorder (Kim & others, 2017).

GENES AND CHROMOSOMES

Genes are not only collaborative, they are enduring. How do genes manage to get passed from generation to generation and end up in all of the trillion cells in the body? The answer lies in three processes that happen at the cellular level: mitosis, meiosis, and fertilization.

Mitosis, Meiosis, and Fertilization All of the cells in your body, except your sperm or eggs, have 46 chromosomes arranged in 23 pairs. These cells reproduce by a process called **mitosis.** During mitosis, the cell's nucleus–including the chromosomes–duplicates itself and the cell divides. Two new cells are formed, each containing the same DNA as the original cell, arranged in the same 23 pairs of chromosomes (Mason, Duncan, & Losos, 2021).

However, a different type of cell division–**meiosis**–forms eggs and sperm (which also are called *gametes*). During meiosis, a cell of the testes (in men) or ovaries (in women) duplicates its chromosomes but then divides twice, thus forming four cells, each of which has only half of the genetic material of the parent cell (Willey & Sandman, 2021). By the end of meiosis, each egg or sperm has 23 *unpaired* chromosomes.

During **fertilization,** an egg and a sperm fuse to create a single cell, called a **zygote** (see Figure 4). In the zygote, the 23 unpaired chromosomes from the egg and the 23 unpaired chromosomes from the sperm combine to form one set of 23 paired chromosomes–one chromosome of each pair from the mother's egg and the other from the father's sperm. In this manner, each parent contributes half of the offspring's genetic material.

Figure 5 shows 23 paired chromosomes of a male and a female. The members of each pair of chromosomes are both similar and different: Each chromosome in the pair contains varying forms of the same genes, at the same location on the chromosome. A gene that influences hair color, for example, is located on both members of one pair of chromosomes, in the same location on each. However, one of those chromosomes might carry a gene associated with blond hair, and the other chromosome in the pair might carry a gene associated with brown hair.

Do you notice any obvious differences between the chromosomes of the male and the chromosomes of the female in Figure 5? The difference lies in the 23rd pair. Ordinarily, in females this pair consists of two chromosomes called X chromosomes; in males the 23rd pair consists of an X and a Y chromosome. The presence of a Y chromosome is one factor that makes a person male rather than female.

FIGURE **4**
A SINGLE SPERM PENETRATING AN EGG AT THE POINT OF FERTILIZATION.
3Dalia/Shutterstock

mitosis Cellular reproduction in which the cell's nucleus duplicates itself; two new cells are formed, each containing the same DNA as the original cell, arranged in the same 23 pairs of chromosomes.

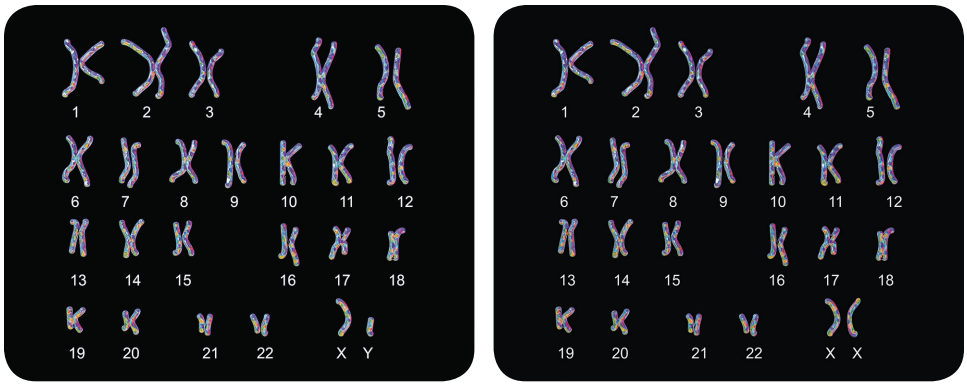
meiosis A specialized form of cell division that occurs to form eggs and sperm (or gametes).

fertilization A stage in reproduction when an egg and a sperm fuse to create a single cell, called a zygote.

zygote A single cell formed through fertilization.

Sources of Variability Combining the genes of two parents in offspring increases genetic variability in the population, which is valuable for a species because it provides more characteristics on which natural selection can operate (Lewis, 2021). In fact, the human genetic process includes several important sources of variability (Brooker, 2021).

First, the chromosomes in the zygote are not exact copies of those in the mother's ovaries or the father's testes. During the formation of the sperm and egg in meiosis, the members of each pair of chromosomes are separated, but which chromosome in the pair goes to the gamete is a matter of chance. In addition, before the pairs separate, pieces of the two chromosomes in each pair are exchanged, creating a new combination of genes on each chromosome (Chess, 2021). Thus, when chromosomes from the mother's egg and the father's sperm are brought together in the zygote, the result is a truly unique combination of genes.



(a) (b)

FIGURE 5

THE GENETIC DIFFERENCE BETWEEN MALES AND FEMALES. Set (*a*) shows the chromosome structure of a male, and set (*b*) shows the chromosome structure of a female. The last pair of 23 pairs of chromosomes is in the bottom right box of each set. Notice that the Y chromosome of the male is smaller than the X chromosome of the female. To obtain this kind of chromosomal picture, a cell is removed from a person's body, usually from the inside of the mouth. The chromosomes are stained by chemical treatment, magnified extensively, and then photographed.
Kateryna Kon/Shutterstock

Another source of variability comes from DNA. Chance, a mistake by cellular machinery, or damage from an environmental agent such as radiation may produce a *mutated gene*, which is a permanently altered segment of DNA.

Even when their genes are identical, however, people vary. The difference between genotypes and phenotypes helps us to understand this source of variability. All of a person's genetic material makes up his or her **genotype.**

There is increasing interest in studying *susceptibility genes*, those that make an individual more vulnerable to accelerated aging or specific diseases such as COVID-19 (Sang & others, 2021), arthritis (Reynard & Barter, 2020), colorectal cancer (Yuan & others, 2021), cardiovascular disease (Liang & others, 2020), and Parkinson disease (Langmyhr & others, 2021), and *longevity genes*, those that make an individual less vulnerable to certain diseases and more likely to live to an older age (Tabibzadeh, 2021; Torres & others, 2021). These are aspects of the individual's genotype.

In the search for longevity genes, Cynthia Kenyon (2010) has extensively studied *C. elegans,* a roundworm, the first animal to have its entire genome sequenced. In early research, Kenyon found that modifying a single gene, *daf-2*, which is linked to hormones, slows aging in the roundworm. She also discovered that another gene, *daf-16,* is necessary for the roundworm to live longer. The *daf-16* gene encodes a gene switch that turns on a number of genes related to stress resistance, immunity, and metabolism (Sun & others, 2020). These genes possibly may extend life by protecting and repairing body tissues (Qi & others, 2021). Other researchers have found that genetic variants in a human *daf-16* version labeled *FOX03A* are linked to increased longevity in a wide range of people, including Americans, Europeans, and Chinese.

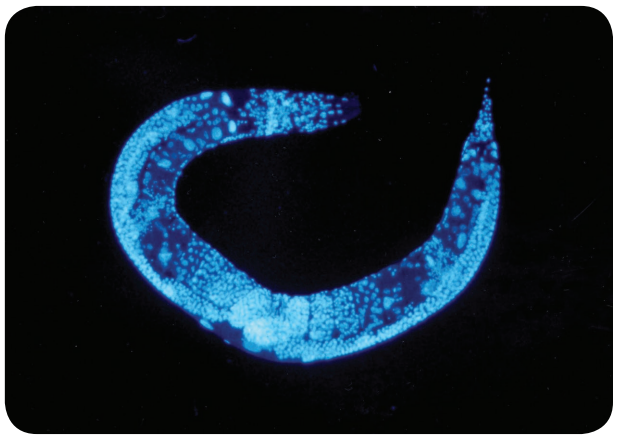
Recent research indicates that *FOXO3A* may serve as a novel blood marker for early detection of Alzheimer disease (Pradhan & others, 2020). Further, *daf-2*-type mutations extend life and slow aging not only in roundworms but also in flies and mice, suggesting that in humans these mutations might contribute to delayed onset and severity of many diseases related to aging, including cancer, cardiovascular disease, and Alzheimer disease (Kenyon, 2010). Recently, Cynthia Kenyon joined a think tank of scientists at Google's Calico (short for California Life Company) division, which seeks to understand the aging process and discover how to modify it. Kenyon believes that interventions to extend the human life span might be possible through the development of drugs that mimic the action of gene mutations that are linked to greater longevity.

However, not all of the genetic material is apparent in an individual's observed and measurable characteristics. A **phenotype** consists of observable characteristics, including physical characteristics (such as height, weight, and hair color) and psychological characteristics (such as personality and intelligence). For each genotype, a range of phenotypes can be expressed, providing another source of variability (Hoefnagels, 2021). An individual can inherit the genetic potential to grow very large, for example, but good nutrition, among other things, will be essential for achieving that potential.

How does the process from genotype to phenotype work? It's highly complex, but at a very basic level DNA information in a cell is transcribed to RNA (ribonucleic acid), which in turn is translated into amino acids that

genotype All of a person's actual genetic material.

phenotype Observable and measurable characteristics of an individual, such as height, hair color, and intelligence.



Researcher Cynthia Kenyon found that modifying a gene called *daf-16* slows the aging in *C. elegans* (shown above). This type of roundworm was the first animal to have its entire genome sequenced.
Washington University, St. Louis/KRT/Newscom

will become proteins (Brooker & others, 2021). Once proteins have been assembled, they become capable of producing phenotype traits and characteristics. Also, environments interact with genotypes to produce phenotypes.

GENETIC PRINCIPLES

What determines how a genotype is expressed to create a particular phenotype? Much is still unknown about the answer to this question. However, a number of genetic principles have been discovered, such as those involving dominant-recessive genes, sex-linked genes, genetic imprinting, and polygenically determined characteristics.

Dominant-Recessive Genes In some cases, one gene of a pair always exerts its effects; it is *dominant*, overriding the potential influence of the other gene, called the *recessive* gene. This is the principle of *dominant-recessive* genes. A recessive gene exerts its influence only if the two genes of a pair are both recessive. If you inherit a recessive gene for a trait from each of your parents, you will show the trait. If you inherit a recessive gene from only one parent, you may never know you carry the gene. Brown hair, farsightedness, and dimples rule over blond hair, nearsightedness, and freckles in the world of dominant-recessive genes.

Can two brown-haired parents have a blond-haired child? Yes, they can. Suppose that each parent has a dominant gene for brown hair and a recessive gene for blond hair. Since dominant genes override recessive genes, the parents have brown hair, but both are *carriers* of blondness and pass on their recessive genes for blond hair. With no dominant gene to override them, the recessive genes can make the child's hair blond.

Sex-Linked Genes Most mutated genes are recessive. When a mutated gene is carried on the X chromosome, the result is called *X-linked inheritance*. It may have very different implications for males and females (Lewis, 2021). Remember that males have only one X chromosome. Thus, if there is an absent or altered disease-relevant gene on the X chromosome, males have no "backup" copy to counter the harmful gene and therefore may develop an X-linked disease. However, females have a second X chromosome, which is likely to be unchanged. As a result, they are not likely to have the X-linked disease. Thus, most individuals who have X-linked diseases are males. Females who have one abnormal copy of the gene on the X chromosome are known as "carriers," and they usually do not show any signs of the X-linked disease. Hemophilia and fragile X syndrome, which we discuss later in this chapter, are examples of X-linked inheritance diseases (Batty & Lillicrap, 2019; Lee & others, 2020).

Genetic Imprinting *Genetic imprinting* occurs when genes have differing effects depending on whether they are inherited from the mother or the father (Klobucar & others, 2020). A chemical process "silences" one member of the gene pair. For example, as a result of imprinting, only the maternally derived copy of a gene might be active, while the paternally derived copy of the same gene is silenced—or vice versa (Germain, Levine, & Chamberlin, 2020). Only a small percentage of human genes appear to undergo imprinting, but it is a normal and important aspect of development. When imprinting goes awry, development is disturbed, as in the case of Beckwith-Wiedemann syndrome (Baker & others, 2019), a growth disorder, and Wilms tumor (Zhang & others, 2020), a type of cancer.

Polygenic Inheritance Genetic transmission is usually more complex than the simple examples we have examined thus far (Brooker, 2021). Few characteristics reflect the influence of only a single gene or pair of genes. Most are determined by the interaction of many different genes; they are said to be *polygenically determined* (Lewis, 2021). Even a simple characteristic such as height, for example, reflects the interaction of many genes as well as the influence of the environment.

The term *gene-gene interaction* is increasingly used to describe studies that focus on the interdependence of two or more genes in influencing characteristics, behavior, diseases, and development. For example, recent studies have documented gene-gene interaction in immune system functioning (Kostel Bal & others, 2020), asthma (Hua & others, 2016), obesity

(Jung & others, 2021), type 2 diabetes (Dominguez-Cruz & others, 2020), cancer (Wu & others, 2021), cardiovascular disease (Deng & others, 2020), arthritis (Fathollahi & others, 2019), alcoholism (Chen & others, 2017), and Alzheimer disease (Li & others, 2020).

CHROMOSOMAL AND GENE-LINKED ABNORMALITIES

Sometimes abnormalities occur during the genetic process. Some of these abnormalities involve whole chromosomes that do not separate properly during meiosis. Other abnormalities are produced by harmful genes.

Chromosomal Abnormalities When a gamete is formed, sometimes the sperm or ovum does not have its normal set of 23 chromosomes. The most notable examples involve Down syndrome and abnormalities of the sex chromosomes (see Figure 6).

Down Syndrome An individual with **Down syndrome** has a round face, a flattened skull, an extra fold of skin over the eyelids, a protruding tongue, short limbs, and intellectual and motor disabilities (Grealish, Price, & Stein, 2020). It is not known why the extra chromosome is present, but the health of the male sperm or the female ovum may be involved.

Down syndrome appears approximately once in every 700 live births. Women between the ages of 16 and 34 are less likely to give birth to a child with Down syndrome than are younger or older women. African American children have a lower rate of Down syndrome than non-Latinx White or Latinx children.

Sex-Linked Chromosomal Abnormalities Recall that a newborn normally has either an X and a Y chromosome or two X chromosomes. Human embryos must possess at least one X chromosome to be viable. The most common sex-linked chromosomal abnormalities involve the presence of an extra chromosome (either an X or Y) or the absence of one X chromosome in females.

Klinefelter syndrome is a chromosomal disorder in which males have an extra X chromosome, making them XXY instead of XY (Vockel & others, 2020). Males with this disorder have undeveloped testes, and they usually have enlarged breasts and become tall. Klinefelter syndrome occurs approximately once in every 1,000 live male births. Only 10 percent of individuals with Klinefelter syndrome are diagnosed before puberty, with the majority not identified until adulthood (Aksglaede & others, 2013).

Down syndrome A chromosomally transmitted form of intellectual disability caused by the presence of an extra copy of chromosome 21.

Klinefelter syndrome A chromosomal disorder in which males have an extra X chromosome, making them XXY instead of XY.

Name	Description	Treatment	Incidence
Down syndrome	An extra chromosome causes mild to severe intellectual disability and physical abnormalities.	Surgery, early intervention, infant stimulation, and special learning programs	1 in 1,900 births at age 20 1 in 300 births at age 35 1 in 30 births at age 45
Klinefelter syndrome (XXY)	An extra X chromosome causes physical abnormalities.	Hormone therapy can be effective	1 in 1,000 male births
Fragile X syndrome	An abnormality in the X chromosome can cause intellectual disability, learning disabilities, or short attention span.	Special education, speech and language therapy	More common in males than in females
Turner syndrome (XO)	A missing X chromosome in females can cause intellectual disability and sexual underdevelopment.	Hormone therapy in childhood and puberty	1 in 2,500 female births
XYY syndrome	An extra Y chromosome can cause above-average height.	No special treatment required	1 in 1,000 male births

FIGURE **6**

SOME CHROMOSOMAL ABNORMALITIES. The treatments for these abnormalities do not necessarily erase the problem but may improve the individual's adaptive behavior and quality of life.

These athletes who have Down syndrome are participating in a Special Olympics competition. Notice the distinctive facial features of the individuals with Down syndrome, such as a round face and a flattened skull. *What causes Down syndrome?*
kali9/Getty Images

Fragile X syndrome (FXS) is a chromosomal disorder that results from an abnormality in the X chromosome, which becomes constricted and often breaks (Zhao & Bhattacharyya, 2020). Mental deficiency frequently is an outcome, but it may take the form of an intellectual disability, autism, a learning disability, or a short attention span (Carroll & others, 2021; McKechanie & others, 2019). This disorder occurs more frequently in males than in females, possibly because the second X chromosome in females negates the effects of the abnormal X chromosome (Stone, Basit, & Los, 2020). A recent study found that a higher level of maternal responsivity to the adaptive behavior of children with FXS had a positive effect on the children's communication skills (Warren & others, 2017).

Turner syndrome is a chromosomal disorder in females in which either an X chromosome is missing, making the person XO instead of XX, or part of one X chromosome is deleted (Bianchi, 2021). Females with Turner syndrome are short in stature and have a webbed neck. They might be infertile and have difficulty in mathematics, but their verbal ability is often quite good. Turner syndrome occurs in approximately 1 of every 2,500 live female births.

The **XYY syndrome** is a chromosomal disorder in which the male has an extra Y chromosome (Berglund & others, 2019). Early interest in this syndrome focused on the belief that the extra Y chromosome found in some males contributed to aggression and violence. However, researchers subsequently found that XYY males are no more likely to commit crimes than are XY males (Witkin & others, 1976). However, while a recent study did not find more cognitive deficits in XYY boys than normal XY boys, they did have more externalizing and internalizing problems (Operto & others, 2019).

Gene-Linked Abnormalities

Abnormalities can be produced not only by an abnormal number of chromosomes but also by harmful genes. More than 7,000 such genetic disorders have been identified, although most of them are rare.

Phenylketonuria (PKU) is a genetic disorder in which the individual cannot properly metabolize phenylalanine, an amino acid. It results from a recessive gene and occurs about once in every 10,000 to 20,000 live births. Today, phenylketonuria is easily detected, and it is treated by a diet that prevents an excess accumulation of phenylalanine (Weiss & others, 2020). If phenylketonuria is left untreated, however, excess phenylalanine builds up in the child, producing intellectual disability and hyperactivity. Phenylketonuria accounts for approximately 1 percent of institutionalized individuals who have an intellectual disability, and it occurs primarily in non-Latinx Whites.

Sickle-cell anemia, which occurs most often in African Americans, is a genetic disorder that impairs the body's red blood cells. Red blood cells carry oxygen to the body's other cells and are usually shaped like a disk. In sickle-cell anemia, a recessive gene causes the red blood cell to become a hook-shaped "sickle" that cannot carry oxygen properly and dies quickly. As a result, the body's cells do not receive adequate oxygen, causing anemia and often early death. About 1 in 400 African American babies is affected by sickle-cell anemia. One in 10 African Americans is a carrier, as is 1 in 20 Latin Americans. Recent research strongly supports the use of hydroxyurea therapy for infants with sickle cell anemia beginning at 9 months of age (Pecker & Lanzkron, 2021). Stem cell transplantation also is being explored as a potential treatment for infants with sickle-cell anemia (Cisneros & Thein, 2020).

Other diseases that result from genetic abnormalities include cystic fibrosis, some forms of diabetes, hemophilia, Alzheimer disease, Huntington disease, spina bifida, and Tay-Sachs disease (Croteau, Wang, & Wheeler, 2021; Eno & others, 2020; Ranganathan & others, 2021; Sharma & others, 2020). Figure 7 provides further information about these diseases. Someday, scientists may identify the origins of these and other genetic abnormalities and discover how to cure them.

Genetic counselors, usually physicians or biologists who are well versed in medical genetics, provide their clients with information regarding the kinds of problems just described

fragile X syndrome (FXS) A chromosomal disorder involving an abnormality in the X chromosome, which becomes constricted and often breaks.

Turner syndrome A chromosomal disorder in females in which either an X chromosome is missing, making the person XO instead of XX, or part of one X chromosome is deleted.

XYY syndrome A chromosomal disorder in which males have an extra Y chromosome.

phenylketonuria (PKU) A genetic disorder in which an individual cannot properly metabolize phenylalanine, an amino acid; PKU is now easily detected—but, if left untreated, results in intellectual disability and hyperactivity.

sickle-cell anemia A genetic disorder that affects the red blood cells and occurs most often in African Americans.

Name	Description	Treatment	Incidence
Cystic fibrosis	Glandular dysfunction that interferes with mucus production; breathing and digestion are hampered, resulting in a shortened life span.	Physical and oxygen therapy, synthetic enzymes, and antibiotics; most individuals live to middle age.	1 in 2,000 births
Diabetes	Body does not produce enough insulin, which causes abnormal metabolism of sugar.	Early onset can be fatal unless treated with insulin.	1 in 2,500 births
Hemophilia	Delayed blood clotting causes internal and external bleeding.	Blood transfusions/injections can reduce or prevent damage due to internal bleeding.	1 in 10,000 males
Huntington's disease	Central nervous system deteriorates, producing problems in muscle coordination and mental deterioration.	Does not usually appear until age 35 or older; death likely 10 to 20 years after symptoms appear.	1 in 20,000 births
Phenylketonuria (PKU)	Metabolic disorder that, left untreated, causes intellectual disability.	Special diet can result in average intelligence and normal life span.	1 in 10,000 to 1 in 20,000 births
Sickle-cell anemia	Blood disorder that limits the body's oxygen supply; it can cause joint swelling, as well as heart and kidney failure.	Penicillin, medication for pain, antibiotics, and blood transfusions.	1 in 400 African American children (lower among other groups)
Spina bifida	Neural tube disorder that causes brain and spine abnormalities.	Corrective surgery at birth, orthopedic devices, and physical/medical therapy.	2 in 1,000 births
Tay-Sachs disease	Deceleration of mental and physical development caused by an accumulation of lipids in the nervous system.	Medication and special diet are used, but death is likely by 5 years of age.	1 in 30 American Jews is a carrier.

FIGURE **7**

Jennifer Leonhard, Genetic Counselor

Jennifer Leonhard is a genetic counselor at Sanford Bemidji Health Clinic in Bemidji, Minnesota. She obtained an undergraduate degree from Western Illinois University and a master's degree in genetic counseling from the University of Arkansas for Medical Sciences.

Genetic counselors like Leonhard work as members of a health care team, providing information and support to families with birth defects or genetic disorders. They identify families at risk by analyzing inheritance patterns and then explore options with the family. Some genetic counselors, like Leonhard, specialize in prenatal and pediatric genetics, while others focus on cancer genetics or psychiatric genetic disorders.

Genetic counselors hold specialized graduate degrees in medical genetics and counseling. They enter graduate school with undergraduate backgrounds from a variety of disciplines, including biology, genetics, psychology, public health, and social work. There are approximately 30 graduate genetic counseling programs in the United States. If you are interested in this profession, you can obtain further information from the National Society of Genetic Counselors at www.nsgc.org.

3 Heredity and Environment Interaction: The Nature-Nurture Debate

LG3 Explain some of the ways that heredity and environment interact to produce individual differences in development.

- Behavior Genetics
- Heredity-Environment Correlations
- The Epigenetic View and Gene × Environment (G × E) Interaction
- Conclusions about Heredity-Environment Interaction

Twin studies compare identical twins with fraternal twins. Identical twins develop from a single fertilized egg that splits into two genetically identical organisms. Fraternal twins develop from separate eggs, making them genetically no more similar than nontwin siblings. *What is the nature of the twin study method?*
Jack Hollingsworth/Getty Images

behavior genetics The field that seeks to discover the influence of heredity and environment on individual differences in human traits and development.

twin study A study in which the behavioral similarity of identical twins is compared with the behavioral similarity of fraternal twins.

adoption study A study in which investigators seek to discover whether, in behavior and psychological characteristics, adopted children are more like their adoptive parents, who provided a home environment, or more like their biological parents, who contributed their heredity. Another form of the adoption study compares adoptive and biological siblings.

Is it possible to untangle the influence of heredity from that of environment and discover the role of each in producing individual differences in development? When heredity and environment interact, how does heredity influence the environment and vice versa?

BEHAVIOR GENETICS

Behavior genetics is the field that seeks to discover the influence of heredity and environment on individual differences in human traits and development. To study the influence of heredity on behavior, behavior geneticists often use either twins or adoption situations (Kendler & others, 2019).

In the most common **twin study,** the behavioral similarity of identical twins (who are genetically identical) is compared with the behavioral similarity of fraternal twins. Recall that although fraternal twins share the same womb, they are no more genetically alike than non-twin siblings. Thus, by comparing groups of identical and fraternal twins, behavior geneticists capitalize on the basic knowledge that identical twins are more similar genetically than are fraternal twins (Herle & others, 2021; Wilson & others, 2020). For example, one study found that conduct problems were more prevalent in identical twins than in fraternal twins; the researchers concluded that the study demonstrated an important role for heredity in conduct problems (Scourfield & others, 2004).

However, several issues complicate interpretation of twin studies. For example, perhaps the environments of identical twins are more similar than the environments of fraternal twins. Parents and other caregivers might stress the similarities of identical twins more than those of fraternal twins, and identical twins might perceive themselves as a "set" and play together more than fraternal twins do. If so, the influence of the environment on the observed similarities between identical and fraternal twins might be highly significant. To read more about identical twins, see *Connecting Development to Life.*

In an **adoption study,** investigators seek to discover whether the behavioral and psychological characteristics of adopted children are more like those of their adoptive parents, who have provided a home environment, or more like those of their biological parents, who have contributed their heredity (Leve & others, 2019). Another form of the adoption study compares adoptive and biological siblings.

connecting development to life

Am I an "I" or "We"?

College freshman Colin Kunzweiler (2007) wrote about his thoughts and experiences related to being an identical twin:

> As a monozygotic individual, I am used to certain things. "Which one are you?" happens to be the most popular question I'm asked, which is almost always followed by "You're Colin. No, wait, you're Andy!" I have two names: one was given to me at birth, the other thrust on me in a random, haphazard way. . . . My twin brother and I are as different from each other as caramel sauce is from gravy. We have different personalities, we enjoy different kinds of music, and I am even taller than he is (by a quarter of an inch). We are different, separate, and individual. I have always been taught that I should maintain my own individuality; that I should be my own person. But if people keep constantly mistaking me for my twin, how can I be my own person with my own identity?

"Am I an 'I' or 'We'?" was the title of an article written by Lynn Perlman (2008) about the struggle twins have in developing a sense of being an individual. Of course, triplets have the same issue, possibly even more strongly so. One set of triplets entered a beauty contest as one person and won the contest!

Perlman, an identical twin herself, is a psychologist who works with twins (her identical twin also is a psychologist). She says that how twins move from a sense of "we" to "I" is a critical task for them as children and sometimes even as adults. For non-twins, separating oneself from a primary caregiver—mother and/or father—is an important developmental task in childhood, adolescence, and emerging adulthood. When a child has a twin, the separation process is likely to be more difficult because of the constant comparison with a twin. Since they are virtually identical in their physical appearance, identical twins are likely to have more problems in distinguishing themselves from their twin than are fraternal twins.

The twin separation process often accelerates in adolescence when one twin is likely to mature earlier than the other (Perlman, 2013). However, for some twins it may not occur until emerging adulthood when they may go to different colleges and/or live apart for the first time. And for some twins, even in adulthood twin separation can be emotionally painful. One 28-year-old identical twin female got a new boyfriend, and the relationship caused a great deal of stress and conflict with her twin sister (Friedman, 2013).

In Lynn Perlman's (2008) view, helping twins develop their own identities should be done on a child-by-child basis, taking into account their preferences and what is in their best interests. She commented that most of the twins she has counseled consider having a twin a positive experience, and while they also are usually strongly attached to each other they are intensely motivated to be considered unique persons.

HEREDITY-ENVIRONMENT CORRELATIONS

The difficulties that researchers encounter when they interpret the results of twin studies and adoption studies reflect the complexities of heredity-environment interaction. Some of these interactions are *heredity-environment correlations*, which means that individuals' genes may be systematically related to the types of environments to which they are exposed (Klahr & Burt, 2014). In a sense, individuals "inherit," seek out, or "construct" environments that may be related or linked to genetic "propensities." Behavior geneticist Sandra Scarr (1993) described three ways that heredity and environment can be correlated (see Figure 8):

Heredity-Environment Correlation	Description	Examples
Passive	Children inherit genetic tendencies from their parents, and parents also provide an environment that matches their own genetic tendencies.	Musically inclined parents usually have musically inclined children and they are likely to provide an environment rich in music for their children.
Evocative	The child's genetic tendencies elicit stimulation from the environment that supports a particular trait. Thus genes evoke environmental support.	A happy, outgoing child elicits smiles and friendly responses from others.
Active (niche-picking)	Children actively seek out "niches" in their environment that reflect their own interests and talents and are thus in accord with their genotype.	Libraries, sports fields, and a store with musical instruments are examples of environmental niches children might seek out if they have intellectual interests in books, talent in sports, or musical talents, respectively.

FIGURE **8**

EXPLORING HEREDITY-ENVIRONMENT CORRELATIONS.

Passive genotype-environment correlations occur because biological parents, who are genetically related to the child, provide a rearing environment for the child. For example, the parents might have a genetic predisposition to be intelligent and read skillfully. Because they read well and enjoy reading, they provide their children with books to read. The likely outcome is that their children, because of both their own inherited predispositions and their book-filled environment, will become skilled readers.

Evocative genotype-environment correlations occur because a child's genetically influenced characteristics elicit certain types of environments. For example, active, smiling children receive more social stimulation than passive, quiet children do. Cooperative, attentive children evoke more pleasant and instructional responses from the adults around them than uncooperative, distractible children do.

Active (niche-picking) genotype-environment correlations occur when children seek out environments that they find compatible and stimulating. *Niche-picking* refers to finding a setting that is suited to one's genetically influenced abilities. Children select from their surrounding environment some aspects that they respond to, learn about, or ignore. Their active selections of environments are related to their particular genotype. For example, outgoing children tend to seek out social contexts in which to interact with people, whereas shy children don't. Children who are musically inclined are likely to select musical environments in which they can successfully perform their skills. How these "tendencies" come about will be explored in our discussion of the epigenetic view.

Scarr notes that the relative importance of the three genotype-environment correlations changes as children develop from infancy through adolescence. In infancy, much of the environment that children experience is provided by adults. Thus, passive genotype-environment correlations are more common in the lives of infants and young children than among older children and adolescents who can extend their experiences beyond the family's influence and create and select their environments to a greater degree.

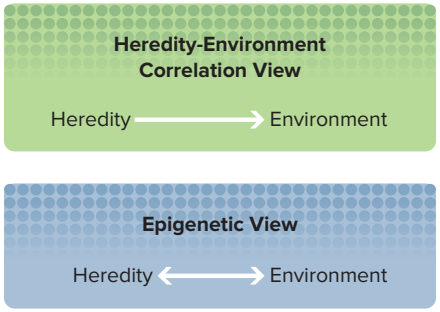

FIGURE **9**

COMPARISON OF THE HEREDITY-ENVIRONMENT CORRELATION AND EPIGENETIC VIEWS.

passive genotype-environment correlations Correlations that exist when the biological parents, who are genetically related to the child, provide a rearing environment for the child.

evocative genotype-environment correlations Correlations that exist when the child's characteristics elicit certain types of environments.

active (niche-picking) genotype-environment correlations Correlations that exist when children seek out environments they find compatible and stimulating.

epigenetic view Perspective emphasizing that development is the result of an ongoing, bidirectional interchange between heredity and environment.

THE EPIGENETIC VIEW AND GENE × ENVIRONMENT (G × E) INTERACTION

In line with the concept of a collaborative gene, Gilbert Gottlieb (2007) proposed an **epigenetic view** which states that development is the result of an ongoing, bidirectional interchange between heredity and the environment. Figure 9 compares the heredity-environment correlation and epigenetic views of development.

Let's look at an example that reflects the epigenetic view. A baby inherits genes from both parents at conception. During prenatal development, toxins, nutrition, and stress can influence some genes to stop functioning while others become more active or less so. During infancy, environmental experiences, such as exposure to toxins, nutrition, stress, learning, and encouragement, continue to modify genetic activity and the activity of the nervous system that directly underlies behavior. Heredity and environment thus operate together—or collaborate—to produce a person's well-being, intelligence, temperament, health, ability to pitch a baseball, reading proficiency, coping skills, and so on (Champagne, 2021; Pagiatakis & others, 2021).

An increasing number of researchers are exploring how the interaction between heredity and environment influences development, including interactions that involve specific DNA sequences (Topart, Werner, & Arimondo, 2020). The epigenetic mechanisms involve the actual molecular modification of the DNA strand as a result of environmental inputs in ways that alter gene functioning (Yang & others, 2021).

Many studies are documenting that people who have the short version of the 5-HTTLPR gene (a gene involving the neurotransmitter serotonin) have an elevated risk of developing depression only if they *also* have very stressful lives. Thus, the specific gene does not directly cause the development of depression; rather the gene interacts with a stressful environment in a way that allows the researchers to predict whether individuals will develop depression (Caspi & others, 2003; Thorne, Ellenbroek, & Day, 2021). For example, a research meta-analysis indicated that the short version of 5-HTTLPR was linked with higher cortisol stress reactivity (Miller & others, 2013). Research studies also have found support for the interaction between the 5-HTTLPR gene and stress levels in predicting depression in adolescents and older adults (Petersen & others, 2012; Zannas & others, 2012). A recent research review concluded that

variations in the 5-HTTLPR gene may contribute to the tendency to ruminate when individuals experience life stress (Scaini & others, 2021). Also, recent studies also have found that carriers of the short version of 5-HTTLPR are at greater risk for depression if they have the following highly stressful diseases: coronary heart disease (Zhang & others, 2020), stroke (Wang & others, 2020), and Parkinson disease (Cheng & others, 2021).

The type of research just described is referred to as studies of **gene × environment (G × E) interaction**—the interaction of a specific measured variation in DNA and a specific measured aspect of the environment (Hoye & others, 2020; Majumdar & others, 2021). Although there is considerable enthusiasm about the concept of gene × environment (G × E) interaction, a research review concluded that this topic of study is plagued by difficulties in replicating results, inflated claims, and other weaknesses (Manuck & McCaffery, 2014). The science of G × E interaction is very young, and in the next several decades it will likely produce more precise findings (Champagne, 2021).

gene × environment (G × E) interaction
The interaction of a specific measured variation in the DNA and a specific measured aspect of the environment.

CONCLUSIONS ABOUT HEREDITY-ENVIRONMENT INTERACTION

If an attractive, popular, intelligent girl is elected president of her high school senior class, is her success due to heredity or to environment? Of course, the answer is "both."

The relative contributions of heredity and environment are not additive. That is, we can't say that such-and-such a percentage of nature and such-and-such a percentage of experience make us who we are. Nor is it accurate to say that full genetic expression happens once, at the time of conception or birth, after which we carry our genetic legacy into the world to see how far it takes us. Genes produce proteins throughout the life span, in many different environments. Or they don't produce these proteins, depending in part on how harsh or nourishing those environments are.

The emerging view is that complex behaviors are influenced by genes in ways that give people a propensity for a particular developmental trajectory (Sallis, Smith, & Munato, 2021). However, the individual's actual development also involves a specific environment. And that environment is complex, just like the mixture of genes we inherit (Bornstein & Esposito, 2021). Environmental influences range from the things we lump together under "nurture" (such as parenting, family dynamics, schooling, and neighborhood quality) to biological encounters (such as viruses, birth complications, and even biological events in cells).

In developmental psychologist David Moore's (2017) view, the biological systems that generate behaviors are extremely complex but too often these systems have been described in overly simplified ways that can be misleading. Thus, although genetic factors clearly contribute to behavior and psychological processes, they don't determine these phenotypes independently from the contexts in which they develop. From Moore's (2017) perspective, it is misleading to talk about "genes for" eye color, intelligence, personality, or other characteristics. Moore commented that in retrospect we should not have expected to be able to make the giant leap from analyzing the molecules in DNA to achieving a complete understanding of human behavior, any more than we should anticipate being able to make the leap from understanding how sound waves move molecules in a concert hall to attaining a full-blown appreciation of a symphony's wondrous experience.

Imagine for a moment that there is a cluster of genes that are somehow associated with youth violence. (This example is hypothetical because we don't know of any such combination.) The adolescent who carries this genetic mixture might experience a world of loving parents, regular nutritious meals, lots of books, and a series of competent teachers. Or the adolescent's world might include parental neglect, a neighborhood in which gunshots and crime are everyday occurrences, and inadequate schooling. In which of these environments are the adolescent's genes likely to manufacture the biological underpinnings of criminality?

If heredity and environment interact to determine the course of development, is that all there is to answering the question of what causes development? Are humans completely at the mercy of their genes and their environment as they develop through the life span? Genetic heritage and environmental experiences are pervasive influences on development. But in thinking about what causes development, consider that development is the co-construction of biology, culture, and the individual. Not only are we the outcomes of our heredity and the

To what extent are this young girl's piano skills likely due to heredity, environment, or both?

4 Prenatal Development

LG4 Characterize the course of prenatal development and its hazards.

- The Course of Prenatal Development
- Prenatal Diagnostic Tests
- Hazards to Prenatal Development
- Prenatal Care

The history of man for nine months preceding his birth would, probably, be far more interesting, and contain events of greater moment, than all three score and ten years that follow it.

—Samuel Taylor Coleridge
English Poet and Essayist, 19th Century

germinal period The period of prenatal development that takes place during the first two weeks after conception; it includes the creation of the zygote, continued cell division, and the attachment of the zygote to the wall of the uterus.

We turn now to a description of how the process of development unfolds from its earliest moment—the moment of *conception*—when two parental cells, with their unique genetic contributions, join to create a new individual.

Conception occurs when a single sperm cell from a male unites with an ovum (egg) in a female's fallopian tube in a process called fertilization. Over the next few months the genetic code discussed earlier directs a series of changes in the fertilized egg, but many events and hazards will influence how that egg develops and becomes a person.

THE COURSE OF PRENATAL DEVELOPMENT

Prenatal development lasts approximately 266 days, beginning with fertilization and ending with birth. It can be divided into three periods: germinal, embryonic, and fetal.

The Germinal Period The **germinal period** is the period of prenatal development that takes place during the first two weeks after conception. It includes the creation of the fertilized egg (the *zygote*), cell division, and the attachment of the zygote to the uterine wall.

Rapid cell division by the zygote begins the germinal period. (Recall from earlier in the chapter that this cell division occurs through a process called *mitosis*.) By approximately one week after conception, the differentiation of these cells—their specialization for different tasks—has already begun. At this stage the group of cells, now called the *blastocyst*, consists of an inner mass of cells that will eventually develop into the embryo, and the *trophoblast*, an outer

layer of cells that later provides nutrition and support for the embryo. *Implantation*, the attachment of the zygote to the uterine wall, takes place about 10 to 14 days after conception.

The Embryonic Period The **embryonic period** of prenatal development occurs from two to eight weeks after conception. During the embryonic period, the rate of cell differentiation intensifies, support systems for cells form, and organs appear.

This period begins as the blastocyst attaches to the uterine wall. The mass of cells is now called an *embryo*, and three layers of cells form. The embryo's *endoderm* is the inner layer of cells, which will develop into the digestive and respiratory systems. The *ectoderm* is the outermost layer, which will become the nervous system, sensory receptors (ears, nose, and eyes, for example), and skin parts (hair and nails, for example). The *mesoderm* is the middle layer, which will become the circulatory system, bones, muscles, excretory system, and reproductive system. Each body part eventually develops from one of these three layers. The endoderm primarily produces internal body parts, the mesoderm primarily produces parts that surround the internal areas, and the ectoderm primarily produces surface parts. **Organogenesis** is the name given to the process of organ formation during the first two months of prenatal development. While they are being formed, the organs are especially vulnerable to environmental influences (Ribatti, Tamma, & Annese, 2021).

As the embryo's three layers form, life-support systems for the embryo develop rapidly. These systems include the amnion, the umbilical cord (both of which develop from the fertilized egg, not the mother's body), and the placenta. The amnion is like a bag or an envelope; it contains a clear fluid in which the developing embryo floats. The amniotic fluid provides an environment that is temperature- and humidity-controlled, as well as shockproof. The *umbilical cord*, which contains two arteries and one vein, connects the baby to the placenta. The *placenta* consists of a disk-shaped group of tissues in which small blood vessels from the mother and the offspring intertwine but do not join.

Very small molecules—oxygen, water, salt, and nutrients from the mother's blood, as well as carbon dioxide and digestive wastes from the baby's blood—pass back and forth between the mother and the embryo or fetus. Virtually any drug or chemical substance the pregnant woman ingests can cross the placenta to some degree, unless it is metabolized or altered during passage, or is too large (Jansson & others, 2020). One study confirmed that ethanol crosses the human placenta and primarily reflects maternal alcohol use (Matlow & others, 2013). Another study revealed that cigarette smoke weakens and increases the oxidative stress of fetal membranes from which the placenta develops (Menon & others, 2011). The stress hormone cortisol also can cross the placenta (Mateos & others, 2018). Large molecules that cannot pass through the placental wall include red blood cells and harmful substances such as most bacteria, maternal wastes, and hormones. The complex mechanisms that govern the transfer of substances across the placental barrier are not entirely understood (Hussey & others, 2020).

The Fetal Period The **fetal period,** which lasts about seven months, is the prenatal period that extends from two months after conception until birth in typical pregnancies. Growth and development continue their dramatic course during this time.

Three months after conception, the fetus is about 3 inches long and weighs about 0.8 ounce. It has become active, moving its arms and legs, opening and closing its mouth, and moving its head. The face, forehead, eyelids, nose, and chin are distinguishable, as are the upper arms, lower arms, hands, and lower limbs. In most cases, the genitals can be identified as male or female. By the end of the fourth month of pregnancy, the fetus has grown to about 5 inches in length and weighs about 3.5 ounces. At this time, a growth spurt occurs in the body's lower parts. For the first time, the mother can feel arm and leg movements.

By the end of the fifth month, the fetus is about 11 inches long and weighs close to a pound. Structures of the skin have formed—toenails and fingernails, for example. The fetus is more active, showing a preference for a particular position in the womb. By the end of the sixth month, the fetus is about 14 inches long and has gained another 6 to 12 ounces. The eyes and eyelids are completely formed, and a fine layer of hair covers the head. A grasping reflex is present and irregular breathing movements occur.

As early as six months of pregnancy (about 24 to 25 weeks after conception), the fetus for the first time has a chance of surviving outside the womb—that is, it is *viable.* Infants that are born early, or between 24 and 37 weeks of pregnancy, usually need help breathing because

embryonic period The period of prenatal development that occurs from two to eight weeks after conception. During the embryonic period, the rate of cell differentiation intensifies, support systems for the cells form, and organs appear.

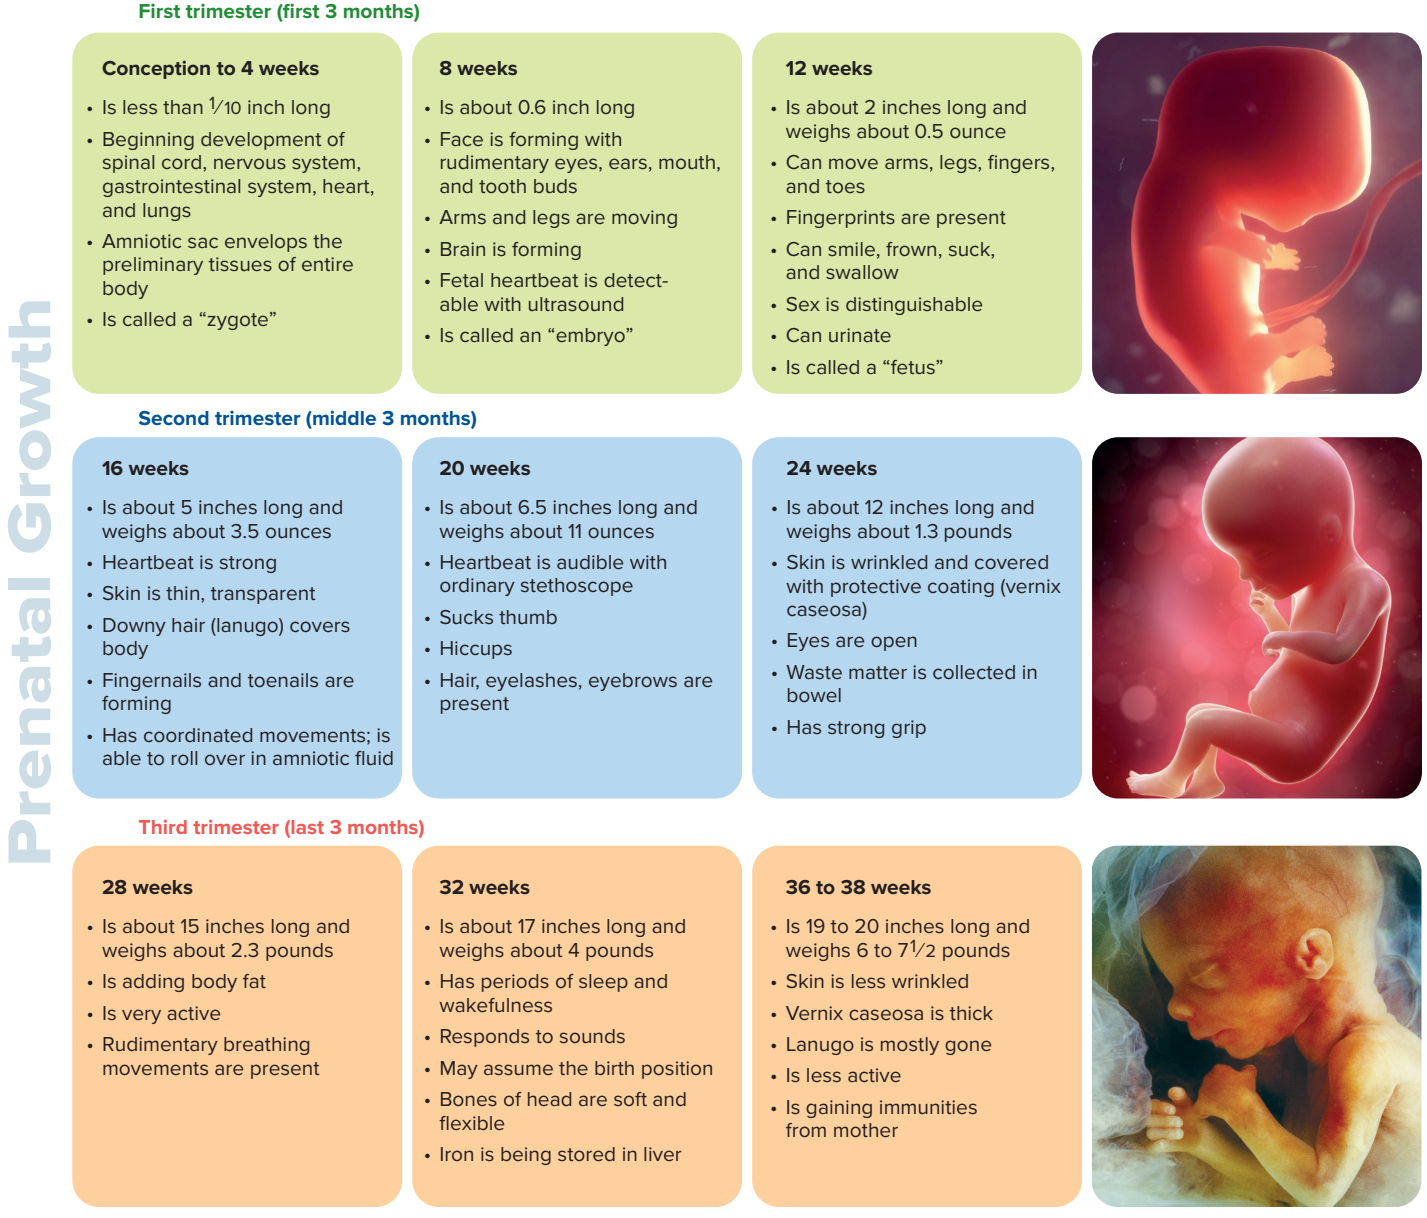
organogenesis Process of organ formation that takes place during the first two months of prenatal development.

fetal period The prenatal period of development that begins two months after conception and lasts for seven months, on average.

their lungs are not yet fully mature. By the end of the seventh month, the fetus is about 16 inches long and weighs about 3 pounds.

During the last two months of prenatal development, fatty tissues develop and the functioning of various organ systems—heart and kidneys, for example—steps up. During the eighth and ninth months, the fetus grows longer and gains substantial weight—about 4 more pounds. At birth, the average American baby weighs 8 pounds and is about 20 inches long.

In addition to describing prenatal development in terms of germinal, embryonic, and fetal periods, prenatal development also can be divided into equal three-month periods, called *trimesters* (see Figure 10). Remember that the three trimesters are not the same as the three prenatal periods we have just discussed. The germinal and embryonic periods occur in the first trimester. The fetal period begins toward the end of the first trimester and continues through the second and third trimesters.



Prenatal Growth
First trimester (first 3 months)
Conception to 4 weeks
• Is less than 1/10 inch long
• Beginning development of spinal cord, nervous system, gastrointestinal system, heart, and lungs
• Amniotic sac envelops the preliminary tissues of entire body
• Is called a "zygote"
8 weeks
• Is about 0.6 inch long
• Face is forming with rudimentary eyes, ears, mouth, and tooth buds
• Arms and legs are moving
• Brain is forming
• Fetal heartbeat is detectable with ultrasound
• Is called an "embryo"
12 weeks
• Is about 2 inches long and weighs about 0.5 ounce
• Can move arms, legs, fingers, and toes
• Fingerprints are present
• Can smile, frown, suck, and swallow
• Sex is distinguishable
• Can urinate
• Is called a "fetus"
Second trimester (middle 3 months)
16 weeks
• Is about 5 inches long and weighs about 3.5 ounces
• Heartbeat is strong
• Skin is thin, transparent
• Downy hair (lanugo) covers body
• Fingernails and toenails are forming
• Has coordinated movements; is able to roll over in amniotic fluid
20 weeks
• Is about 6.5 inches long and weighs about 11 ounces
• Heartbeat is audible with ordinary stethoscope
• Sucks thumb
• Hiccups
• Hair, eyelashes, eyebrows are present
24 weeks
• Is about 12 inches long and weighs about 1.3 pounds
• Skin is wrinkled and covered with protective coating (vernix caseosa)
• Eyes are open
• Waste matter is collected in bowel
• Has strong grip
Third trimester (last 3 months)
28 weeks
• Is about 15 inches long and weighs about 2.3 pounds
• Is adding body fat
• Is very active
• Rudimentary breathing movements are present
32 weeks
• Is about 17 inches long and weighs about 4 pounds
• Has periods of sleep and wakefulness
• Responds to sounds
• May assume the birth position
• Bones of head are soft and flexible
• Iron is being stored in liver
36 to 38 weeks
• Is 19 to 20 inches long and weighs 6 to 7 1/2 pounds
• Skin is less wrinkled
• Vernix caseosa is thick
• Lanugo is mostly gone
• Is less active
• Is gaining immunities from mother

FIGURE 10

THE THREE TRIMESTERS OF PRENATAL DEVELOPMENT. Both the germinal and embryonic periods occur during the first trimester. The end of the first trimester as well as the second and third trimesters are part of the fetal period.

The Brain One of the most remarkable aspects of the prenatal period is the development of the brain (Thomasson, 2020; Yamada, Kanazawa, & Kuniyoshi, 2021). By the time babies are born, they have approximately 100 billion **neurons,** or nerve cells, which handle information processing at the cellular level in the brain. During prenatal development, neurons move to specific locations and start to become connected. The basic architecture of the human brain is assembled during the first two trimesters of prenatal development. Typically, the third trimester of prenatal development and the first two years of postnatal life are characterized by connectivity and functioning of neurons (Vasung & others, 2019).

Four important phases of the brain's development during the prenatal period involve (1) the neural tube, (2) neurogenesis, (3) neural migration, and (4) neural connectivity.

Neural Tube As the human embryo develops inside its mother's womb, the nervous system begins forming as a long, hollow tube located on the embryo's back. This pear-shaped *neural tube,* which forms at about 21 days after conception, develops out of the ectoderm. The tube closes at the top and bottom by about 27 days after conception (Keunen, Counsell, & Benders, 2017). Figure 11 shows that the nervous system still has a tubular appearance six weeks after conception.

Two birth defects related to a failure of the neural tube to close are anencephaly and spina bifida. When fetuses have *anencephaly* (that is, when the head end of the neural tube fails to close), the highest regions of the brain fail to develop and death occurs in the womb, during childbirth, or shortly after birth. *Spina bifida*, an incomplete development of the spinal cord, results in varying degrees of paralysis of the lower limbs (Pinquart, 2020). Individuals with spina bifida usually need assistive devices such as crutches, braces, or wheelchairs. A strategy that can help to prevent neural tube defects is for pregnant women to consume adequate amounts of the B vitamin folic acid (Li & others, 2020). A large-scale study in Brazil found that when flour was fortified with folic acid it produced a significant reduction in neural tube defects (Santos & others, 2016). Also, a recent global analysis concluded that mandatory folic acid fortification of flour or wheat was reaching only 23 percent of total possible prevention (Kancherla & others, 2021).

Both maternal diabetes and obesity place the fetus at risk for developing neural tube defects (Cooper & Yang, 2020). Researchers also have found that a high level of maternal stress is linked to neural tube defects (Mowla & others, 2020).

Neurogenesis In a normal pregnancy, once the neural tube has closed, a massive proliferation of new immature neurons begins to take place at about the fifth prenatal week. The generation of new neurons is called *neurogenesis*, which continues through the remainder of the prenatal period although it is largely complete by the end of the fifth month after conception (Borsani & others, 2019). At the peak of neurogenesis, it is estimated that as many as 200,000 neurons are being generated every minute!

Neural Migration At approximately 15 weeks after conception, *neural migration* occurs (Keunen, Counsell, & Benders, 2017). Cells begin moving outward from their point of origin to their appropriate locations and creating the different levels, structures, and regions of the brain (Miyazaki, Song, & Takahashi, 2016). Once a cell has migrated to its target destination, it must mature and develop a more complex structure.

Neural Connectivity At about the 23rd prenatal week, connections between neurons begin to form, a process that continues postnatally (Borsani & others, 2019). We will have much more to say about the structure of neurons, their connectivity, and the development of the infant brain in the chapter on "Physical Development and Biological Aging."

PRENATAL DIAGNOSTIC TESTS

Together with her doctor, a pregnant woman will decide the extent to which she should undergo prenatal testing. A number of tests can indicate whether a fetus is developing normally; these include ultrasound sonography, fetal MRI, chorionic villus sampling, amniocentesis, and maternal blood screening. The decision to have a given test depends on several criteria, such as the mother's age, medical history, and genetic risk factors.

Ultrasound Sonography An ultrasound test is generally performed 7 weeks into a pregnancy and at various times later in pregnancy. *Ultrasound sonography* is a noninvasive prenatal medical procedure in which high-frequency sound waves are directed into the pregnant woman's abdomen (Santirocco & others, 2020). The echo from the sounds is transformed into a visual representation of the fetus's inner structures. This technique can detect many structural abnormalities in the fetus, including microcephaly, a form of intellectual disability involving an abnormally small brain; it can also give clues to the baby's sex and indicate whether there is more than one fetus (Kaymak & others, 2020). A research review concluded that many aspects of the developing prenatal brain can be detected by ultrasound in the first trimester and that about 50 percent of spina bifida cases can be identified at this time, most of these being severe cases (Engels & others, 2016). There is virtually no risk to the woman or fetus in using ultrasound. Ultrasound results are available as soon as the images are read by a radiologist.

Fetal MRI The development of brain-imaging techniques has led to increasing use of *fetal MRI* to diagnose fetal malformations (Wilson & others, 2021) (see Figure 12). MRI (magnetic resonance imaging) uses a powerful magnet and radio waves to generate detailed images of the body's organs and structures. Currently, ultrasound is still the first choice in fetal screening, but fetal MRI can provide more detailed images than ultrasound (Torrents-Barrena & others, 2021; van der Knoop & others, 2020). In many instances, ultrasound will indicate a possible abnormality and fetal MRI will then be used to obtain a clearer, more detailed image (Tee & others, 2016). Among the fetal malformations that fetal MRI may be able to detect better than ultrasound sonography are certain abnormalities of the central nervous system, chest, gastrointestinal tract, genital/urinary tract, and placenta (Marini & others, 2020; Qu & others, 2021).

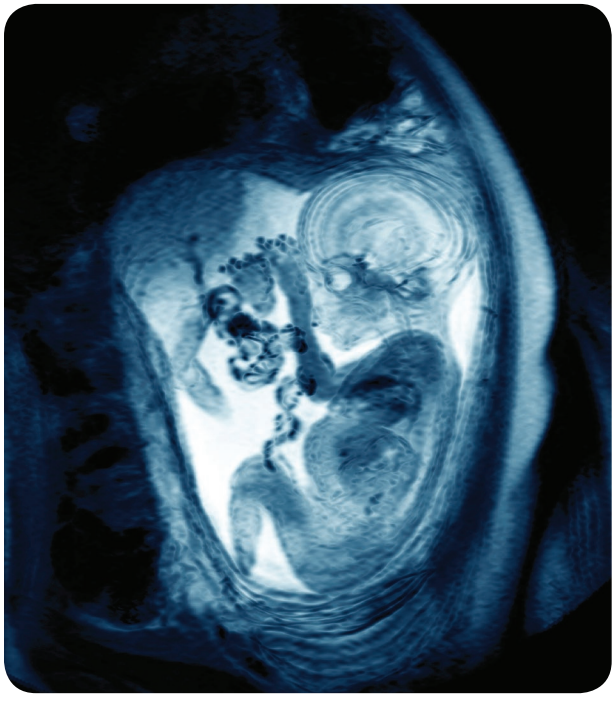

FIGURE **12**
A FETAL MRI, WHICH IS INCREASINGLY BEING USED IN PRENATAL DIAGNOSIS OF FETAL MALFORMATIONS.
Du Cane Medical Imaging Ltd/Science Source

Chorionic Villus Sampling At some point between the tenth and twelfth weeks of pregnancy, chorionic villus sampling may be used to screen for genetic defects and chromosomal abnormalities. *Chorionic villus sampling* (*CVS*) is a prenatal medical procedure in which a tiny tissue sample from the placenta is removed and analyzed (Gimovsky & others, 2020). The results are available in about 10 days.

Amniocentesis Between the 15th and 18th weeks of pregnancy, *amniocentesis* may be performed. In this procedure, a sample of amniotic fluid is withdrawn by syringe and tested for chromosomal or metabolic disorders (Xiang & others, 2020; Zemet & others, 2021). The later in the pregnancy amniocentesis is performed, the better its diagnostic potential. However, the earlier it is performed, the more useful it is in deciding how to handle a pregnancy when the fetus is found to have a disorder. It may take two weeks for enough cells to grow so that amniocentesis test results can be obtained. Amniocentesis brings a small risk of miscarriage: about 1 woman in every 200 to 300 miscarries after amniocentesis.

Maternal Blood Screening and Cell-Free Fetal DNA During the sixteenth to eighteenth weeks of pregnancy, maternal blood screening may be performed. *Maternal blood screening* identifies pregnancies that have an elevated risk for birth defects such as spina bifida and Down syndrome, as well as congenital heart disease risk for children (Novak & Graham, 2019). A current blood test, the *triple screen*, measures three substances in the mother's blood in the second trimester of pregnancy. After an abnormal triple screen result, the next step is usually an ultrasound examination. If an ultrasound does not explain the abnormal triple screen results, amniocentesis typically is used.

Recent advances in molecular genetics and DNA sequencing have improved the effectiveness of noninvasive testing to detect genetic abnormalities using cell-free fetal DNA in the mother's blood (Guseh, 2020; Yasa & others, 2021). The cell-free fetal DNA testing has especially improved the accuracy of prenatal testing for fetal abnormalities such as Down syndrome as early as 10 weeks into the first trimester.

Fetal Sex Determination Chorionic villus sampling has often been used to determine the sex of the fetus at some point between 11 and 13 weeks of gestation. Recently, though, some noninvasive techniques have been able to detect the sex of the fetus at an earlier point (Kazachkova & others, 2019). Recently, non-invasive diagnosis of plasma was able to accurately determine fetal sex at 4.5 weeks (D'Aversa & others, 2018). However, being able to detect an offspring's sex as well as the presence of various diseases and defects at such an early stage raises ethical concerns about couples' motivation to terminate a pregnancy (Bowman-Smart & others, 2020).

HAZARDS TO PRENATAL DEVELOPMENT

For most babies, the course of prenatal development goes smoothly. Their mother's womb protects them as they develop. Despite this protection, however, the environment can affect the embryo or fetus in many well-documented ways.

General Principles A **teratogen** is any agent that can potentially cause a birth defect or negatively alter cognitive and behavioral outcomes. The field of study that investigates the causes of birth defects is called *teratology* (Yin & others, 2021). Teratogens include drugs, incompatible blood types, environmental pollutants, infectious diseases, nutritional deficiencies, maternal stress, advanced maternal and paternal age, and environmental pollutants.

The dose, the genetic susceptibility, and the time of exposure to a particular teratogen influence both the severity of the damage to an embryo or fetus and the type of defect:

- ***Dose*** The dose effect is obvious—the greater the dose of an agent, such as a drug, the greater the effect.
- ***Genetic Susceptibility*** The type or severity of abnormalities caused by a teratogen is linked to the genotype of the pregnant woman and the genotype of the embryo or fetus. For example, how a mother metabolizes a particular drug can influence the degree to which the drug's effects are transmitted to the embryo or fetus. Differences in placental membranes and placental transport also affect exposure. The extent to which an embryo or fetus is vulnerable to a teratogen may also depend on its genotype (Yang & others, 2021). Also, for unknown reasons, male fetuses are far more likely to be affected by teratogens than female fetuses are.
- ***Time of Exposure*** Teratogens do more damage at some points in development than at others. Damage during the germinal period may even prevent implantation. In general, the embryonic period is more vulnerable than the fetal period (Thomasson, 2020).

Figure 13 summarizes additional information about the effects of time of exposure to a teratogen. The probability of a structural defect is greatest early in the embryonic period, when organs are being formed. Each body structure has its own critical period of formation (a fixed time period very early in development during which certain experiences or events can have a long-lasting effect on development). The critical period for the nervous system (week 3) is earlier than that for arms and legs (weeks 4 and 5).

After organogenesis is complete, teratogens are less likely to cause anatomical defects. Instead, exposure during the fetal period is more likely to stunt growth or to create problems in the way organs function. To examine some key teratogens and their effects, let's begin with drugs.

teratogen Any agent that can potentially cause a birth defect or negatively alter cognitive and behavioral outcomes.

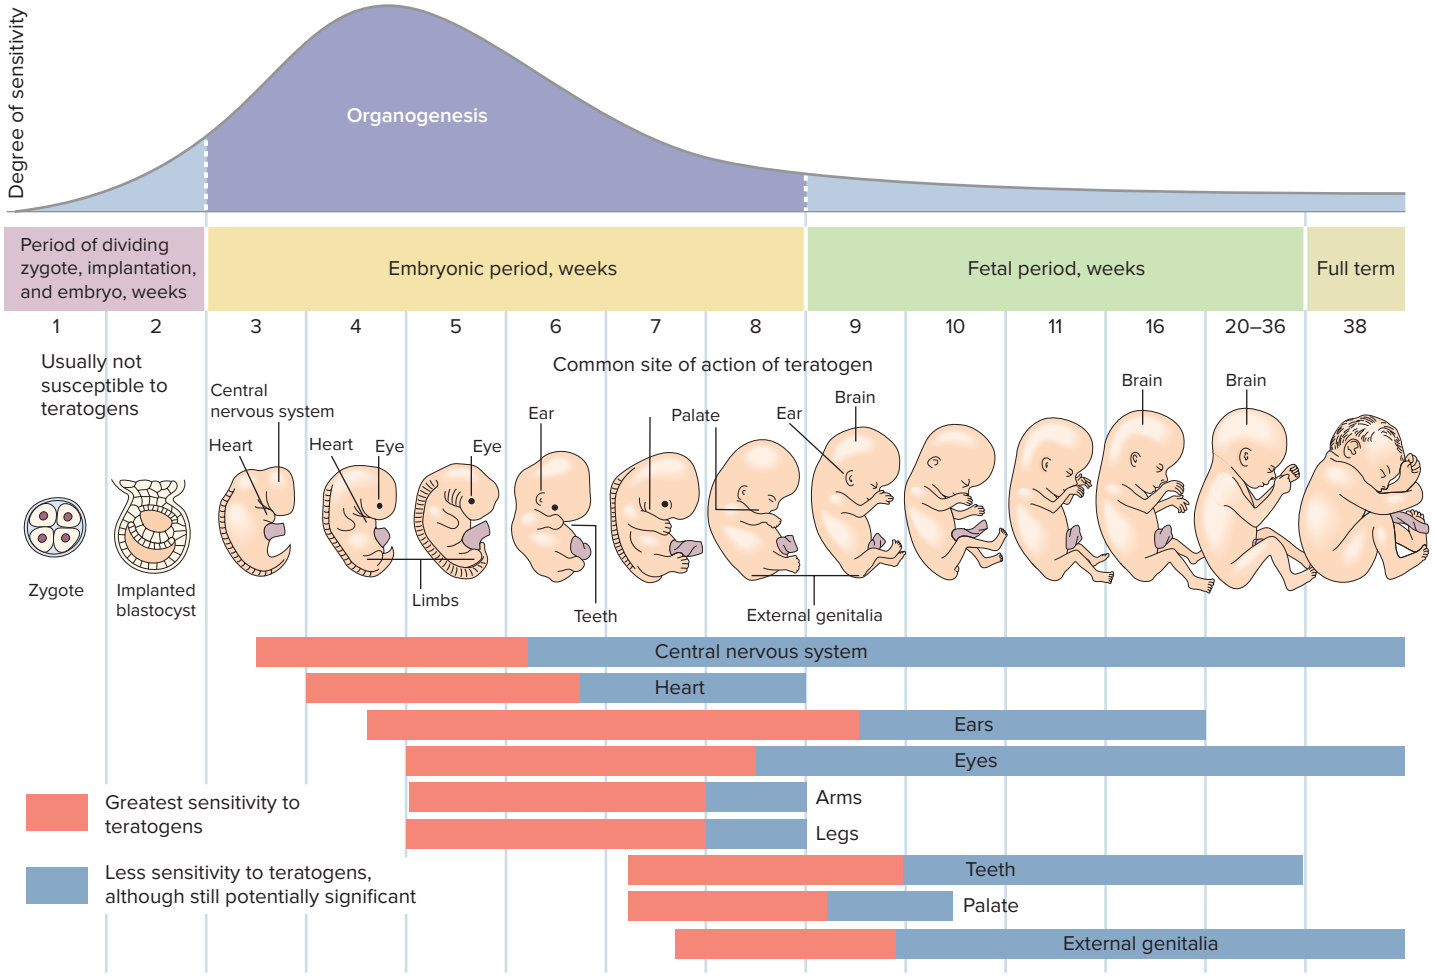

FIGURE 13

TERATOGENS AND THE TIMING OF THEIR EFFECTS ON PRENATAL DEVELOPMENT. The danger of structural defects caused by teratogens is greatest early in embryonic development. The period of organogenesis (red color in the bar graph) lasts for about six weeks. Later assaults by teratogens (blue color in the bar graph) mainly occur in the fetal period and instead of causing structural damage are more likely to stunt growth or cause problems with organ function.

Prescription and Nonprescription Drugs Prescription drugs that can function as teratogens include antibiotics, such as streptomycin and tetracycline; some antidepressants; certain hormones, such as progestin and synthetic estrogen; and isotretinoin (Accutane™, often prescribed for acne) (Altintas Aykan & Ergun, 2020). Among the birth defects caused by Accutane are heart defects, eye and ear abnormalities, and brain malformations. In a review of teratogens that should never be taken during the first trimester of pregnancy, isotreninoin was on the prohibited list (Eltonsy & others, 2016). Nonprescription drugs that can be harmful include diet pills and high doses of aspirin.

Psychoactive Drugs *Psychoactive drugs* are drugs that act on the nervous system to alter states of consciousness, modify perceptions, and change moods. Examples include caffeine, alcohol, nicotine, and marijuana, as well as illegal drugs such as cocaine.

Caffeine People often consume caffeine by drinking coffee, tea, colas, or energy drinks, or by eating chocolate. A recent review of 17 meta-analyses concluded that maternal caffeine consumption during pregnancy is linked to a higher occurrence of miscarriage, stillbirth, low birth weight, and childhood acute leukemia (James, 2021). Also, another recent meta-analysis found that higher maternal caffeine intake during pregnancy was associated with childhood overweight and obesity (Jin & Qiao, 2021). In addition, the effects of maternal consumption of energy drinks that typically have extremely high levels of caffeine have not yet been studied.

The U.S. Food and Drug Administration recommends that pregnant women either not consume caffeine or consume it only sparingly.

Alcohol Heavy drinking by pregnant women can be devastating to offspring (Baker & Stoler, 2020; Flannigan & others, 2021). **Fetal alcohol spectrum disorders (FASD)** are a cluster of abnormalities and problems that appear in the offspring of mothers who drink alcohol heavily during pregnancy (Carter, Jacobson, & Jacobson, 2020; Popova & others, 2021). The abnormalities include facial deformities and defective limbs, face, and heart. Most children with FASD have learning problems, and many are below average in intelligence; some have an intellectual disability (Khoury & Milligan, 2019). In recent research, children with ADHD had impairments in verbal comprehension, perceptual-motor coordination, processing speed, attention, executive function, and language development (Lange & others, 2021). Also, in one study, FASD was associated with both externalized and internalized behavior problems in childhood (Tsang & others, 2016). Further, in a recent study in the United Kingdom, the life expectancy of individuals with FASD was only 34 years of age, about 42 percent of the life span of members of the general population (Thanh & Jonsson, 2016). In this study, the most common causes of death among individuals with FASD were suicide (15 percent), accidents (14 percent), and poisoning by illegal drugs or alcohol (7 percent). A recent study confirmed the significant risk of suicidal behavior in adolescents with FASD (O'Connor & others, 2019). Although mothers of FASD infants are heavy drinkers, many mothers who are heavy drinkers may not have children with FASD or may have one child with FASD and other children who do not have it.

What are some guidelines for alcohol use during pregnancy? Even drinking just one or two servings of beer or wine or one serving of hard liquor a few days a week can have negative effects on the fetus, although it is generally agreed that this level of alcohol use will not cause fetal alcohol spectrum disorders (American Society for Reproductive Medicine & others, 2019). The U.S. Surgeon General recommends that no alcohol be consumed during pregnancy, as does the French Alcohol Society (Rolland & others, 2016). Despite such recommendations, a recent large-scale U.S. study found that 11.5 percent of adolescent and 8.7 percent of adult pregnant women reported using alcohol in the previous month (Oh & others, 2017).

However, in Great Britain, the National Institutes of Care and Health Excellence have concluded that consuming one to two alcoholic drinks not more than twice a week is safe during pregnancy (O'Keeffe, Greene, & Kearney, 2014). A study of more than 7,000 7-year-olds found that children born to mothers who were light drinkers during pregnancy (up to two drinks per week) did not show more developmental problems than children born to nondrinking mothers (Kelly & others, 2013).

Nicotine Cigarette smoking by pregnant women can adversely influence prenatal development, birth, and postnatal development (Suter & Aagaard, 2020). Preterm births and low birth weights, fetal and neonatal deaths, respiratory problems, sudden infant death syndrome (SIDS), and cardiovascular problems are more common among the offspring of mothers who smoked during pregnancy (Elliott & others, 2020). Prenatal smoking has been implicated in as many as 25 percent of infants with low birth weight (Brown & Graves, 2013). A recent study also found a number of negative cognitive and behavioral outcomes in the infant's first year of life as a consequence of prenatal cigarette exposure: negative moods, poorer attention, greater excitability, and more irritability (Froggatt, Covey, & Reissland, 2020). Also, a recent study revealed that maternal cigarette smoking during pregnancy was associated with lower academic achievement in offspring at 16 years of age (Kendler & others, 2021). And in a recent study, maternal cigarette smoking during pregnancy was linked to higher rates of cigarette smoking among offspring at 16 years of age (De Genna & others, 2016). In addition, researchers have found that maternal smoking during pregnancy is a risk factor for the development of attention deficit hyperactivity disorder (ADHD) in offspring (Andersson & others, 2020). A recent meta-analysis of 15 studies concluded that smoking during pregnancy increased the risk of children having ADHD, and the risk of ADHD was greater if mothers were heavy smokers (Huang & others, 2018). Further, a study revealed that daughters whose mothers had smoked during their pregnancy were more likely to subsequently smoke during their own pregnancy (Ncube & Mueller, 2017).

Despite the plethora of negative outcomes for maternal smoking during pregnancy, a large-scale U.S. study revealed that 23 percent of adolescent and 15 percent of adult pregnant

Fetal alcohol spectrum disorders (FASD) are characterized by a number of physical abnormalities and learning problems. Notice the wide-set eyes, flat cheekbones, and thin upper lip in this child with FASD.

women reported using tobacco in the previous month (Oh & others, 2017). Cessation of smoking by pregnant women by the third trimester is linked to improved birth outcomes (Crume, 2019). And a recent analysis concluded that smoking cessation at any point during pregnancy benefits the fetus (American College of Obstetricians and Gynecologists, 2020). Also in this analysis, the greatest benefit occurred when smoking cessation took place before 15 weeks of gestation.

Researchers have documented that environmental tobacco smoke is associated with negative outcomes for offspring (Gould & others, 2020). Maternal exposure to environmental tobacco smoke, or secondhand smoke, has been linked to an increased risk of low birth weight (Salama & others, 2013), preterm birth (Chen & others, 2021), and to diminished ovarian functioning in female offspring (Kilic & others, 2012). Also, one study revealed that environmental tobacco smoke was associated with 114 deregulations of gene expression, especially those involving immune functioning, in the fetal cells of offspring (Votavova & others, 2012). Another study found that maternal exposure to environmental tobacco smoke during prenatal development increased the risk of stillbirth (Varner & others, 2014).

A final point about nicotine use during pregnancy involves the recent dramatic increase in the use of e-cigarettes (Rollins & others, 2020). In a recent study, chronic exposure to e-cigarette aerosols was linked to low birth weight in offspring (Orzabal & others, 2019).

Cocaine Does cocaine use during pregnancy harm the developing embryo and fetus? One research study found that cocaine quickly crossed the placenta to reach the fetus (De Giovanni & Marchetti, 2012). The most consistent finding is that cocaine exposure during prenatal development is associated with reduced birth weight, length, and head circumference (Gouin & others, 2011). In other studies, prenatal cocaine exposure has been linked to impaired connectivity of the thalamus and prefrontal cortex in newborns (Salzwedel & others, 2016); lower arousal, less effective self-regulation, higher excitability, and lower quality of reflexes at 1 month of age (Ackerman, Riggins, & Black, 2010; Lester & others, 2002); self-regulation problems at age 12 (Minnes & others, 2016); impaired motor development at 2 years of age and a slower rate of growth through 10 years of age (Richardson, Goldschmidt, & Williford, 2008); elevated blood pressure at 9 years of age (Shankaran & others, 2010); impaired language development and information processing (Beeghly & others, 2006); attention deficit hyperactivity disorder (Richardson & others, 2016); increased likelihood of being in a special education program that offers support services (Levine & others, 2008); increased behavioral problems, especially externalizing problems such as high rates of aggression and delinquency (Minnes & others, 2010; Richardson & others, 2016); and posttraumatic stress disorder (PTSD) (Richardson & others, 2016). Further, in a longitudinal study prenatal cocaine exposure was linked to early use of marijuana, arrest history, conduct disorder, and emotion regulation problems at 21 years of age (Richardson & others, 2019).

Some researchers argue that these findings should be interpreted cautiously (Accornero & others, 2007). Why? Because other factors in the lives of pregnant women who use cocaine (such as poverty, malnutrition, and other substance abuse) often cannot be ruled out as possible contributors to the problems found in their children (Messiah & others, 2011). For example, cocaine users are more likely than nonusers to smoke cigarettes, use marijuana, drink alcohol, and take amphetamines.

Despite these cautions, the weight of research evidence indicates that children born to mothers who use cocaine are likely to have neurological, medical, and cognitive deficits (Baer & others, 2019; Martin & others, 2016; Richardson & others, 2018). Cocaine use by pregnant women is never recommended.

Marijuana An increasing number of studies find that marijuana use by pregnant women also has negative outcomes for their offspring (Maia & others, 2020; Nashed, Hardy, & Laviolette, 2021). In a meta-analysis, marijuana use during pregnancy was linked to offsprings' low birth weight and a greater likelihood of requiring care in a neonatal intensive care unit (NICU) (Gunn & others, 2016). In other research, newborns born to mothers who had used marijuana during pregnancy were more likely to be born preterm or low birth weight (Haight & others, 2021; Petrangelo & others, 2019). Also, a recent study found that marijuana use by pregnant women was associated with an increase in chronic obstructive pulmonary disease when their children were 4 years old (Villarreal & others, 2019). Further, another study found that prenatal marijuana exposure was related to lower intelligence in children (Goldschmidt

& others, 2008). Researchers also have found that marijuana use during pregnancy is associated with lower levels of attention, memory, and impulse control in offspring (Wu, Jew, & Lu, 2011). And recently marijuana use during pregnancy has been linked to higher levels of psychopathology (internalizing and externalizing problems in offspring) as well as a lower level of gray matter volume in the brain (Paul & others, 2021). Further, another study indicated that prenatal exposure to marijuana was linked to marijuana use at 14 years of age (Day, Goldschmidt, & Thomas, 2006). In sum, marijuana use is not recommended for pregnant women (Martin, 2020).

There is considerable concern about likely increased marijuana use by pregnant women in states where marijuana use is no longer illegal. In a recent study, marijuana use by pregnant women increased from 6 to 11 percent after its use was legalized in California (Lee & others, 2021).

Synthetic Opioids and Opiate-Related Pain Killers An increasing number of women are using synthetic opioids, such as fentanyl, and opiate-related pain relievers obtained legally by prescription (such as OxyContin and Vicodin) during their pregnancy (Carlier & others, 2020). Infants born to women using these substances during pregnancy are at risk for experiencing opioid withdrawal. Other possible outcomes for children exposed to these substances are just beginning to be studied (National Institute of Drug Abuse, 2021). Any prolonged use of synthetic opioids and opiate-related pain relievers is not recommended (U.S. Food and Drug Administration, 2021).

Maternal Diseases Maternal diseases and infections can produce defects in offspring by crossing the placental barrier, or they can cause damage during birth (Suter & Aagaard, 2020). Rubella (German measles) is one disease that can cause prenatal defects. One study found that cardiac defects, pulmonary problems, and microcephaly (a condition in which the baby's head is significantly smaller and less developed than average) were among the most common fetal and neonatal outcomes when women had rubella during pregnancy (Yazigi & others, 2017). Women who plan to have children should have a blood test before they become pregnant to determine whether they are immune to the disease.

Syphilis (a sexually transmitted infection) is more damaging later in prenatal development—four months or more after conception. When syphilis is present at birth, problems can develop in the central nervous system and gastrointestinal tract (Rodriguez & others, 2021). Penicillin is the only known treatment for syphilis during pregnancy (Moline & Smith, 2016).

Another infection that has received widespread attention recently is genital herpes. Newborns contract this virus when they are delivered through the birth canal of a mother with genital herpes (Egan & others, 2020). If an active case of genital herpes is detected in a pregnant woman close to her delivery date, a cesarean section (in which the infant is delivered through an incision in the mother's abdomen) can be performed to keep the virus from infecting the newborn.

AIDS is a sexually transmitted infection that is caused by the human immunodeficiency virus (HIV), which destroys the body's immune system. A mother can infect her offspring with HIV/AIDS in three ways: (1) across the placenta during gestation, (2) through contact with maternal blood or fluids during delivery, and (3) through breast feeding. The transmission of AIDS through breast feeding is a particular problem in many developing countries (UNICEF, 2021). Babies born to HIV-infected mothers can be (1) infected and symptomatic (show HIV symptoms), (2) infected but asymptomatic (show no HIV symptoms), or (3) not infected at all. An infant who is infected and asymptomatic may still develop HIV symptoms up to 15 months of age.

Because the fetus depends entirely on its mother for nutrition, it is important for the pregnant woman to have good nutritional habits. In Kenya, this government clinic provides pregnant women with information about how their diet can influence the health of their fetus and offspring. *What might the information about diet be like?*
Delphine Bousquet/AFP/Getty Images

Maternal Diet and Nutrition A developing embryo or fetus depends completely on its mother for nutrition, which comes from the mother's blood (Vander Wyst & others, 2020). The nutritional status of the embryo or fetus is determined by

How do pregnant women's emotional states and stress levels affect prenatal development and birth?
Skynesher/E+/Getty Images

the mother's total caloric intake as well as her intake of proteins, vitamins, and minerals. Children born to malnourished mothers are more likely than other children to be malformed.

Being overweight before and during pregnancy can also put the embryo or fetus at risk, and an increasing number of pregnant women in the United States are overweight (Dow & Szymanski, 2020; Mate & others, 2021). Maternal obesity adversely affects pregnancy outcomes through elevated rates of hypertension, diabetes, respiratory complications, infections in the mother, and depression (Meghelli & others, 2020). A recent analysis concluded that approximately one-third of women of reproductive age are obese (Moholdt & Hawley, 2020). Research studies have found that maternal obesity is linked to an increase in stillbirth (Gardosi & others, 2013), asphyxia-related complications in preterm infants (Mitha & others, 2020), and an increased likelihood that the newborn will require care in a neonatal intensive care unit (Kutchi, Chellammal, & Akila, 2020). Further, a research review concluded that maternal obesity during pregnancy is associated with an increased likelihood of offspring being obese in childhood and adulthood (Pinto Pereira & others, 2016). Management of obesity that includes weight loss and increased exercise prior to pregnancy is likely to benefit the mother and the baby (Mate & others, 2021; Menichini & others, 2020).

One aspect of maternal nutrition that is important for normal prenatal development is folic acid, a B-complex vitamin. As indicated earlier in the chapter, lack of folic acid is related to neural tube defects in offspring (Kancherla & others, 2021; Li & others, 2020). The U.S. Department of Health and Human Services (2021) recommends that pregnant women consume a minimum of 400 micrograms of folic acid per day (about twice the amount the average woman gets in one day). Orange juice and spinach are examples of foods that are rich in folic acid.

Emotional States and Stress When a pregnant woman experiences intense fears, anxieties, and other emotions or negative mood states, physiological changes occur that may affect her fetus (Dempsey & Saxton, 2021). A mother's stress may also influence the fetus indirectly by increasing the likelihood that the mother will engage in unhealthy behaviors such as taking drugs and receiving poor prenatal care.

High maternal anxiety and stress during pregnancy can have long-term consequences for the offspring (Monk & others, 2020). One study found that high levels of depression, anxiety, and stress during pregnancy were linked to internalizing problems in adolescence (Betts & others, 2014). A research review indicated that pregnant women with high levels of stress are at increased risk for having a child with emotional or cognitive problems, attention deficit hyperactivity disorder (ADHD), and language delay (Taige & others, 2007). Further, a research review concluded that regardless of the form of maternal prenatal stress or anxiety and the prenatal trimester in which the stress or anxiety occurred, during the first two years of life the offspring displayed lower levels of self-regulation (Korja & others, 2017). Also, a recent study indicated that higher maternal pregnancy-related anxiety was linked to more emotional symptoms, peer relationship problems, and overall child difficulties at 4 years of age (Acosta & others, 2019). And a recent study found that individuals whose mothers reported a higher level of stress during pregnancy have an increased risk of developing psychological disorders, such as mood disorders, later in life (Brannigan & others, 2019).

Maternal depression also can have an adverse effect on birth outcomes and children's development (Dias & Figueiredo, 2020). Research indicates that maternal depression during pregnancy is linked to preterm birth and low birth weight (Mparmpakas & others, 2013). One study found that maternal depression during pregnancy was associated with low birth weight in full-term offspring (Chang & others, 2014). Another study found that taking antidepressants early in pregnancy was linked to an increased risk of miscarriage (Almeida & others, 2016). Researchers have also found that when fetuses were exposed to serotonin-based antidepressants, they were more likely to be born preterm (Podrebarac & others, 2017). Further, a study revealed that taking antidepressants in the second or third trimester of pregnancy was linked to an increased risk of autism spectrum disorders in children (Boukhris & others, 2016). A recent meta-analysis indicated that yoga was effective in reducing depressive symptoms in pregnant women (Ng & others, 2019).

Maternal Age When possible harmful effects on the fetus and infant are considered, two maternal age groups are of special interest: adolescents and

developmental **connection**
Sexuality
Adolescent pregnancy creates negative developmental trajectories for mothers and their offspring. Connect to "Gender and Sexuality."

What are some of the risks for infants born to adolescent mothers?
Barbara Penoyar/Photodisc/Getty Images

women 35 years of age and older (Attali & Yogev, 2021; Kawakita & others, 2016). The mortality rate of infants born to adolescent mothers is double that of infants born to mothers in their twenties. Adequate prenatal care decreases the probability that a child born to an adolescent girl will have physical problems. However, adolescents are the least likely age group to obtain prenatal assistance from clinics and health services.

Maternal age is also linked to the risk that a child will have Down syndrome (LeFevre & Sundermeyer, 2020). A baby with Down syndrome rarely is born to a mother 16 to 34 years of age. However, when the mother reaches 40 years of age, the probability is slightly over 1 in 100 that a baby born to her will have Down syndrome, and by age 50 it is almost 1 in 10. When mothers are 35 years and older, risks also increase for low birth weight, preterm delivery, and fetal death (Frick, 2021). Also, in a recent study, pregnant women aged 43 years and older were more likely to have infants who were stillborn (Wu & others, 2019). Further, recent research indicates that pregnancy after 35 years of age is associated with hypertension, diabetes, and having a cesarean section (Montori & others 2021). Also, the risks of fetal death, neonatal ICU admission, and postpartum hemorrhage are greater when pregnancy occurs after 40 years of age (Montori & others, 2021).

We still have much to learn about the effects of the mother's age on pregnancy and childbirth. As women remain active, exercise regularly, and are careful about their nutrition, their reproductive systems may remain healthier at older ages than was thought possible in the past.

Environmental Hazards Many aspects of our modern industrial world can endanger the embryo or fetus. Some specific hazards to the embryo or fetus include radiation, toxic wastes, and other chemical pollutants.

Women and their physicians should weigh the risk of undergoing an X-ray when the woman is or might be pregnant (Baysinger, 2010). However, a routine diagnostic X-ray of a body area other than the abdomen, with the woman's abdomen protected by a lead apron, is generally considered safe (Brent, 2009, 2011).

An explosion at the Chernobyl nuclear power plant in the Ukraine produced radioactive contamination that spread to surrounding areas. Thousands of infants were born with health problems and deformities as a result of the nuclear contamination, including this boy whose arm did not form. *Other than radioactive contamination, what are some other types of environmental hazards to prenatal development?*
Sergey Guneev/RIA Novosti

Paternal Factors So far, we have discussed how characteristics of the mother—such as drug use, disease, diet and nutrition, age, and emotional states—can influence prenatal development and the development of the child. Might there also be some paternal risk factors? Indeed, there are several (Mayo & others, 2019; Montagnoli & others, 2021). Men's exposure to lead, radiation, certain pesticides, and petrochemicals may cause abnormalities in sperm that lead to miscarriage or diseases such as childhood cancer (Cordier, 2008). The father's smoking during the mother's pregnancy also can cause problems for the offspring (Agricola & others, 2016). A research review concluded that tobacco smoking is linked to impaired male fertility, as well as increased DNA damage, aneuploidy (abnormal number of chromosomes in a cell), and mutations in sperm (Beal, Yauk, & Marchetti, 2017). Also, a recent study found that compared to non-users, daily e-cigarette smokers had a lower sperm count (Holmboe & others, 2020). In another study, heavy paternal smoking was associated with increased risk of early miscarriage (Venners & others, 2004). In a recent meta-analysis, paternal smoking prior to and during pregnancy was linked to increased rates of childhood leukemia (Cao, Lu, & Lu, 2020). In addition, a research review concluded that there is an increased risk of spontaneous abortion (miscarriage), autism, and schizophrenic disorders when the father is 40 years of age or older (Liu & others, 2012). And a research study revealed that children born to fathers who were 40 years of age or older had increased risk of developing autism because of an increase in random gene mutations in older fathers (Kong & others, 2012). However, the age of the offspring's mother was not linked to development of autism in children.

The father may contribute to positive outcomes for the fetus by providing support and having a positive attitude toward the pregnancy (Braren & others, 2020). Earlier, you read about how

In one study in China, the longer fathers smoked, the greater the risk that their children would develop cancer (Ji and others, 1997). *What are some other paternal factors that can influence the development of the fetus and the child?*
David Butow/Corbis Historical/Getty Images

maternal stress and depression have negative developmental outcomes for offspring. Fathers can play an important role in helping mothers keep their stress and depression levels lower by contributing to a positive marital relationship, not engaging in spousal abuse, sharing more in household tasks, and participating in childbirth classes. A recent study found the mother's perceived stress during pregnancy was elevated when the father was physically and verbally aggressive toward her (Kashanian & others, 2021). Also, her perceived stress during pregnancy was lower when he was emotionally and financially supportive and when he participated in prenatal care visits.

PRENATAL CARE

Although prenatal care varies enormously from one woman to another, it usually involves a defined schedule of visits for medical care, which typically includes screening for manageable conditions and treatable diseases that can affect the baby or the mother. In addition to medical care, prenatal programs often include comprehensive educational, social, and nutritional services (Hartman & others, 2020). Information about pregnancy, labor, delivery, and caring for the newborn can be especially valuable for first-time mothers. Prenatal care is also very important for women in poverty and immigrant women because it links them with other social services (Fryer & others, 2021). Further, there are ethnic disparities in prenatal care and pregnancy. African American and Native American/Alaska Native women are two to three times more likely than non-Latinx White women to die of pregnancy-related causes (Petersen & others, 2019). Research indicates that African American and Latinx women are much less likely to initiate prenatal care in the first trimester of pregnancy and also are less likely than non-Latinx White women to get adequate prenatal care (Green, 2018). By far the main reasons for these ethnic disparities are lower socioeconomic status factors such as education and income. Also, a recent study indicated that African American and Latinx women reported almost twice as many barriers to prenatal care as non-Latinx White women (Fryer & others, 2021).

An innovative program that is rapidly expanding in the United States is CenteringPregnancy (Heberlein & others, 2020). This program is relationship-centered and provides complete prenatal care in a group setting (Hetherington & others, 2018). It replaces traditional 15-minute physician visits with 90-minute peer group support sessions and self-examination led by a physician or certified nurse-midwife. Groups of up to 10 women (and often their partners) meet regularly beginning at 12 to 16 weeks of pregnancy. The sessions emphasize empowering women to play an active role in experiencing a positive pregnancy. Research increasingly shows positive outcomes of CenteringPregnancy for the fetus and child, as well as the mother (Darby-Stewart & Strickland, 2019). A recent large-scale study compared women who participated in CenteringPregnancy with women who received individual prenatal care at a university medical center (Cunningham & others, 2019). Women who participated in CenteringPregnancy were less likely to have preterm or low birth weight offspring. In another recent study, women who participated in CenteringPregnancy used pain relief less during labor and were more likely to breast feed their infants (Rijnders & others, 2019).

The increasingly widespread CenteringPregnancy program alters routine prenatal care by bringing women out of exam rooms and into relationship-oriented groups.
MBI/Alamy Stock Photo

Exercise increasingly is recommended as part of a comprehensive prenatal care program (Barakat, 2021; McDonald & others, 2021). Exercise during pregnancy helps prevent constipation, conditions the body, reduces excessive weight gain, lowers the risk of developing hypertension, and is associated with a more positive mental state, including a reduced level of depression (Lee & others, 2020). For example, in a recent meta-analysis, yoga was effective in reducing depressive symptoms in pregnant women (Ng & others, 2019). Further, one study indicated that pregnant women who did not exercise three or more times a week were more likely to develop hypertension (Barakat & others, 2017). Also, a recent study indicated that pregnant women who exercised regularly in the second and third trimesters rated their quality of life higher (Krzepota, Sadowska, & Biernat, 2018). Further, regular exercise during pregnancy has benefits for the fetus and infant. For example, a recent research review concluded that regular exercise is linked to a lower incidence of preterm birth (Mate & others, 2020). And a recent study found that women's regular exercise during pregnancy was linked to more advanced development of the neonatal brain (Laborte-Lemoyne, Currier, & Ellenberg, 2017).

5 Birth and the Postpartum Period

LG5 Summarize how birth takes place and describe the nature of the postpartum period.

The Birth Process | The Transition from Fetus to Newborn | Low Birth Weight and Preterm Infants | Bonding | The Postpartum Period

The long wait for the moment of birth is over, and the infant is about to appear. What happens during childbirth, and what can be done to make the experience a positive one? Nature writes the basic script for how birth occurs, but parents make important choices about the conditions surrounding birth. We will look first at the sequence of physical steps through which a child is born.

There was a star danced, and under that I was born.

—William Shakespeare
English Playwright, 17th Century

THE BIRTH PROCESS

The birth process occurs in three stages. It may take place in different contexts and in most cases involves one or more attendants.

Stages of Birth The first stage of the birth process is the longest. Uterine contractions are 15 to 20 minutes apart at the beginning and last up to a minute each. These contractions cause the woman's cervix to stretch and open. As the first stage progresses, the contractions come closer together, occurring every two to five minutes. Their intensity increases. By the end of the first stage, contractions dilate the cervix to an opening of about 10 centimeters (4 inches), so that the baby can move from the uterus to the birth canal. For a woman having her first child, the first stage lasts an average of 6 to 12 hours; for subsequent children, this stage typically is much shorter.

The second birth stage begins when the baby's head starts to move through the cervix and the birth canal. It terminates when the baby emerges completely from the mother's body. With each contraction, the mother bears down hard to push the baby out of her body. By the time the baby's head is out of the

After the long journey of prenatal development, birth takes place. During birth the baby is on a threshold between two worlds. *What are the characteristics of the three stages of birth?*

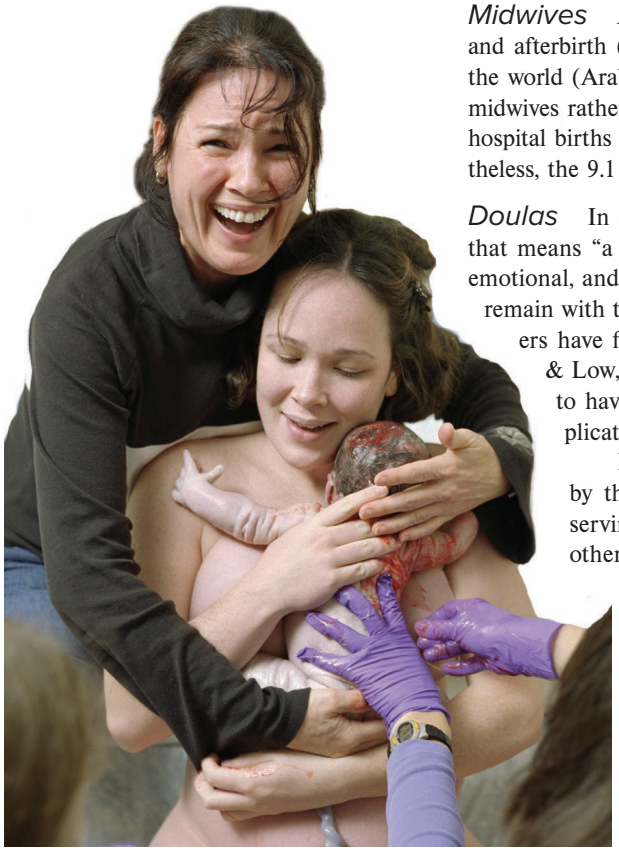
Viviane Moos/Corbis Historical/Getty Images

mother's body, the contractions come almost every minute and last for about a minute each. This stage typically lasts approximately 45 minutes to an hour.

Afterbirth is the third stage, during which the placenta, umbilical cord, and other membranes are detached and expelled from the uterus. This final stage is the shortest of the three birth stages, lasting only a few minutes.

Childbirth Setting and Attendants In 2017 in the United States, 98.4 percent of births took place in hospitals, 0.99% occurred in homes, and 0.52 percent happened in birth centers (MacDorman & Declercq, 2019). The percentage of U.S. births at home is the highest since reporting of this context began in 1989. An increase in home births has occurred mainly among non-Latinx White women, especially those who were older and married. For these non-Latinx White women, two-thirds of their home births are attended by a midwife.

In U.S. hospitals, it has become the norm for the baby's father or a birth coach to be with the mother throughout labor and delivery. In the East African Nigoni culture, by contrast, men are completely excluded from the childbirth process. When a woman is ready to give birth, female relatives move into the woman's hut and the husband leaves, taking his belongings (clothes, tools, weapons, and so on) with him. He is not permitted to return until after the baby is born. In some cultures, childbirth is an open, community affair. For example, in the Pukapukan culture in the Pacific Islands, women give birth in a shelter that is open to villagers, who may observe the birth.



A doula assists a birth. *What types of support do doulas provide?*
Andersen Ross/Getty Images

Midwives A *midwife* is a trained health practitioner who helps women during labor, delivery, and afterbirth (Stevens & Alonso, 2021). Midwifery is practiced in most countries throughout the world (Arabi & others, 2018). In Holland, more than 40 percent of babies are delivered by midwives rather than by doctors. However, in the United States, in 2017 only 9.1 percent of all hospital births were attended by a midwife (National Center for Health Statistics, 2019). Nonetheless, the 9.1 percent figure represents a substantial increase from less than 1 percent in 1975.

Doulas In some countries, a doula attends a childbearing woman. *Doula* is a Greek word that means "a woman who helps." A **doula** is a caregiver who provides continuous physical, emotional, and educational support for the mother before, during, and after childbirth. Doulas remain with the parents throughout labor, assessing and responding to their needs. Researchers have found positive effects when a doula is present at the birth of a child (Howard & Low, 2020). One study found that doula-assisted mothers were four times less likely to have a low birth weight baby and two times less likely to experience a birth complication involving themselves or their baby (Gruber, Cupito, & Dobson, 2013).

In the United States, most doulas work as independent service providers hired by the expectant parents. Doulas typically function as part of a "birthing team," serving as an adjunct to the midwife or the hospital's obstetric staff (O'Rourke & others, 2020).

doula A caregiver who provides continuous physical, emotional, and educational support for the mother before, during, and after childbirth.

Methods of Childbirth U.S. hospitals often allow the mother and her obstetrician a range of options regarding the method of delivery. Key choices involve the use of medication, whether to use any of a number of nonmedicated techniques to reduce pain, and when to have a cesarean delivery.

Medication Three basic kinds of drugs that are used for labor are analgesia, anesthesia, and oxytocin/Pitocin. *Analgesia* is used to relieve pain (Hotoft & Maimburg, 2021). Analgesics include tranquilizers, barbiturates, and narcotics such as Demerol.

Predicting how a drug will affect an individual woman and her fetus is difficult (Tesemma, Sori, & Gemeda, 2020). A particular drug might have only a minimal effect on one fetus yet have a much stronger effect on another. The drug's dosage is also a factor. Higher doses of tranquilizers and narcotics given to decrease the mother's pain potentially have a more negative effect on the fetus than do lower doses. It is important for the mother to assess her level of pain and have a voice in deciding whether or not she should receive medication.

Natural and Prepared Childbirth For a brief time not long ago, the idea of avoiding all medication during childbirth gained favor in the United States. Instead, many women chose to reduce the pain of childbirth through techniques known as natural childbirth and prepared childbirth. Today, at least some medication is used in the typical childbirth, but elements of natural childbirth and prepared childbirth remain popular (Bacon & Tomich, 2017).

Natural childbirth is a childbirth method in which no drugs are given to relieve pain or assist in the birth process. The mother and her partner are taught to use breathing methods and relaxation techniques during delivery. French obstetrician Ferdinand Lamaze developed a method similar to natural childbirth that is known as **prepared childbirth,** or the Lamaze method (Walsh, 2018). It includes a special breathing technique to control pushing in the final stages of labor, as well as detailed education about anatomy and physiology (Wu & others, 2021). The Lamaze method has become very popular in the United States. The pregnant woman's partner usually serves as her labor coach; he attends childbirth classes with her and guides her breathing and relaxation during labor and delivery. In sum, proponents of current prepared childbirth methods conclude that when information and support are provided, women know how to give birth.

An instructor conducts a Lamaze class. *What characterizes the Lamaze method of prepared childbirth?*
Stockbroker/MBI/Alamy Stock Photo

natural childbirth A childbirth method that attempts to reduce the mother's pain by decreasing her fear through education about childbirth stages and relaxation techniques during delivery.

prepared childbirth Developed by French obstetrician Ferdinand Lamaze, a childbirth strategy similar to natural childbirth but one that teaches a special breathing technique to control pushing in the final stages of labor and provides details about anatomy and physiology.

Other Nonmedicated Techniques to Reduce Pain The effort to reduce stress and control pain during labor has recently led to an increase in the use of some older and some newer nonmedicated techniques (Carlsson & Ulfsdottir, 2020; Ghanbari-Homayi & others, 2021). These include waterbirth, massage, and acupuncture.

Waterbirth involves giving birth in a tub of warm water. Some women go through labor in the water and get out for delivery; others remain in the water for delivery. The rationale for waterbirth is that the baby has been in an amniotic sac for many months and therefore delivery in a similar environment is likely to be less stressful for the baby and the mother (Clews, Church, & Ekberg, 2020). Mothers get into the warm water when contractions become closer together and more intense. Getting into the water too soon can cause labor to slow or stop. An increasing number of studies indicate that waterbirth is a positive experience (Fair & others, 2020). For example, in a recent Swedish study, women who gave birth in water had a lower risk of vaginal tears, shorter labor, needed fewer drugs for pain relief and interventions for medical problems, and rated their birth experience more positively than women who had conventional spontaneous vaginal births (Ulfsdottir, Saltvedt, & Georgsson, 2018). Also, in a recent U.S. study of almost 27,000 births, women giving birth in water had more favorable outcomes including fewer prolonged first- and second-stage labors and less hemorrhaging (Snapp & others, 2020). Also in this study, newborns born in water were less likely be admitted to a NICU, to have fetal heart rate abnormalities, or to experience respiratory complications. And in a recent review of seven studies, women who used waterbirth described it as a positive experience (Feeley, Cooper, & Burns, 2021). Waterbirth has been practiced more often in European countries such as Switzerland and Sweden than in the United States in recent decades, but it is increasingly being included in U.S. birth plans.

What characterizes the use of waterbirth in delivering a baby?
Judy Lawrance/Alamy Stock Photo

Massage is increasingly used prior to and during delivery (Withers, Kharazmi, & Lim, 2018). Researchers have found that massage therapy reduces pain during labor (Gallo & others, 2018; Shahoei & others, 2017). For example, a recent study found that lower back massage reduced

What characterizes the transition from fetus to newborn?
ERproductions Ltd/Blend Images LLC

women's labor pain and increased their satisfaction with the birth experience (Unalmis Erdogan, Yanikkerem, & Goker, 2017).

Acupuncture, the insertion of very fine needles into specific locations in the body, is used as a standard procedure to reduce the pain of childbirth in China, although it only recently has begun to be used for this purpose in the United States and Europe (Mollart & others, 2019; Takahashi, 2021). Research indicates that acupuncture can have positive effects on labor and delivery (Citkovitz, Schnyer, & Hoskins, 2011).

Cesarean Delivery Normally, the baby's head comes through the vagina first. But if the baby is in a *breech position,* its buttocks are the first part to emerge from the vagina. In 1 of every 25 deliveries, the baby's head is still in the uterus when the rest of the body is out. Because breech births can cause respiratory problems, if the baby is in a breech position a surgical procedure known as a cesarean delivery is usually performed. In a *cesarean* delivery (or cesarean section), the baby is removed from the uterus through an incision made in the mother's abdomen. The most common causes of cesarean delivery are failure to progress through labor (which can be slowed by epidural anesthesia, for example) and fetal distress.

More cesarean deliveries are performed in the United States than in any other country in the world. In 2018, 31.9 percent of U.S. births were cesarean deliveries (Martin & others, 2019). The benefits and risks of cesarean deliveries continue to be debated in the United States and around the world (Panda, Begley, & Daly, 2020; Rudey, do Carmo Leal, & Rego, 2021).

THE TRANSITION FROM FETUS TO NEWBORN

Much of our discussion of birth so far has focused on the mother. However, birth also involves considerable stress for the baby. If the delivery takes too long, the baby can develop *anoxia*, a condition in which the fetus or newborn receives insufficient oxygen. Anoxia can cause brain damage.

The baby has considerable capacity to withstand the stress of birth. Large quantities of adrenaline and noradrenaline, hormones that protect the fetus in the event of oxygen deficiency, are secreted in the newborn's body during the birth process (Van Beveren, 2021).

Immediately after birth, the umbilical cord is cut and the baby begins to breathe on its own. Before birth, oxygen came from the mother via the umbilical cord, but a full-term baby's lungs are sufficiently developed to support independent breathing.

Apgar Scale A widely used method to assess the health of newborns at one and five minutes after birth; it evaluates an infant's heart rate, respiratory effort, muscle tone, body color, and reflex irritability.

Almost immediately after birth, a newborn is weighed, cleaned up, and tested for signs of developmental problems that might require urgent attention. The **Apgar Scale** is widely used to assess the health of newborns at one and five minutes after birth. The Apgar Scale evaluates infants' heart rate, respiratory effort, muscle tone, body color, and reflex irritability (see Figure 14). An obstetrician or nurse does the evaluation and gives the newborn a score, or reading,

Score	0	1	2
Heart rate	Absent	Slow—less than 100 beats per minute	Fast—100–140 beats per minute
Respiratory effort	No breathing for more than one minute	Irregular and slow	Good breathing with normal crying
Muscle tone	Limp and flaccid	Weak, inactive, but some flexion of extremities	Strong, active motion
Body color	Blue and pale	Body pink, but extremities blue	Entire body pink
Reflex irritability	No response	Grimace	Coughing, sneezing and crying

FIGURE **14**

THE APGAR SCALE. A newborn's score on the Apgar Scale indicates whether the baby has urgent medical problems.

Linda Pugh, Perinatal Nurse

Perinatal nurses work with childbearing women to support health and growth during the childbearing experience. Linda Pugh, Ph.D., R.N.C., is a perinatal nurse on the faculty at The Johns Hopkins University School of Nursing. She is certified as an inpatient obstetric nurse and specializes in the care of women during labor and delivery. She teaches undergraduate and graduate students, educates professional nurses, and conducts research. In addition, Pugh consults with hospitals and organizations about women's health issues and many of the topics we discuss in this chapter. Her research interests include implementing nursing interventions with low-income breast-feeding women, discovering ways to prevent and ameliorate fatigue during childbearing, and using breathing exercises during labor.

Linda Pugh *(right)* assists a mother and her newborn infant.
Courtesy Dr. Linda Pugh

of 0, 1, or 2 on each of these five health signs. A total score of 7 to 10 indicates that the newborn's condition is good. A score of 5 indicates that there may be developmental difficulties. A score of 3 or below signals an emergency and warns that the baby might not survive. The Apgar Scale is especially good at assessing the newborn's ability to respond to the stress of delivery and to adapt to its new environment (Hotoft & Maimburg, 2020). It also identifies high-risk infants who need resuscitation. Recent studies have found that low Apgar scores are associated with long-term additional support needs in education and reductions in educational attainment (Tweed & others, 2016), risk of developmental vulnerability at 5 years of age (Razaz & others, 2016), and risk of developing ADHD (Hanc & others, 2018). Further, a recent study found that Apgar scores at 5 and 10 minutes after birth provide information about preterm infants' ability to survive (Cnattingius, Johansson, & Razaz, 2020).

Nurses often play important roles in the birth of a baby. To read about the work of a nurse who specializes in caring for women during labor and delivery, see *Connecting with Careers*.

LOW BIRTH WEIGHT AND PRETERM INFANTS

Three related conditions pose threats to many newborns: low birth weight, preterm birth, and being small for date. **Low birth weight infants** weigh less than 5 pounds 8 ounces at birth. *Very low birth weight* newborns weigh less than 3 pounds 4 ounces, and *extremely low birth weight* newborns weigh less than 2 pounds 3 ounces. **Preterm infants** are born three weeks or more before the pregnancy has reached its full term—in other words, 35 or fewer weeks after conception. **Small for date infants** (also called *small for gestational age infants*) have a birth weight that is below normal when the length of the pregnancy is considered. They weigh less than 90 percent of all babies of the same gestational age. Small for date infants may be preterm or full term. One study found that small for date infants have a 400 percent greater risk of death (Regev & others, 2003).

In 2018, 10 percent of U.S. infants were born preterm—a significant increase since the 1980s (Martin & others, 2019). The

FIGURE **15**

PERCENTAGE OF INFANTS BORN WITH LOW BIRTH WEIGHT IN SELECTED COUNTRIES.

increase in preterm births is likely due to such factors as the increasing number of births to women 35 years of age or older, increasing rates of multiple births, increased management of maternal and fetal conditions (for example, inducing labor preterm if medical technology indicates that it will increase the likelihood of survival), increased rates of substance abuse (including tobacco and alcohol), and increased stress. Ethnic variations characterize preterm birth. In 2018, the likelihood of being born preterm in the United States was 9 percent for non-Latinx White infants, but the rate was 14 percent for African American infants and 10 percent for Latinx infants (Martin & others, 2019). The lowest preterm birth rate was for Asian American infants (8.5 percent) in 2018.

Most, but not all, preterm babies are also low birth weight babies. The incidence of low birth weight varies considerably from country to country. In some countries, such as India and Sudan, where poverty is rampant and the health and nutrition of mothers are poor, the rate of low birth weight babies is as high as 31 percent (see Figure 15). In the United States, there has been an increase in low birth weight infants in the last two decades, and the U.S. low birth weight rate of 8.3 percent in 2018 is considerably higher than that of many other developed countries (Martin & others, 2019). For example, only 4 percent of the infants born in Sweden, Finland, Norway, and Korea are low birth weight, and only 5 percent of those born in New Zealand, Australia, and France are low birth weight. As with preterm birth, ethnic variations characterize low birth weight, with 13.9 percent of African American babies born with low birth weight compared to 7.5 percent of Latinx and 6.9 percent of non-Latinx White infants (Martin & others, 2019).

Consequences of Being Born Preterm and Low Birth Weight

Although most preterm and low birth weight infants are healthy, as a group they have more health and developmental problems than do infants of normal birth weight. For preterm birth, the terms *extremely preterm* and *very preterm* are increasingly used (Webb & others, 2014). *Extremely preterm infants* are those born at less than 28 weeks gestation, and *very preterm infants* are those born between 28 and 33 weeks of gestational age.

The number and severity of health problems increase when infants are born very early and very small (Gallini & others, 2021). In a recent Japanese study of very low birth weight infants (VLBW), 6.2 percent were born with birth defects, with the most common being chromosomal abnormalities, heart defects, and malformation of the digestive system (Kawasaki & others, 2021). The most common diseases in the VLBW infants were Down syndrome and cleft palate. Survival rates for infants who are born very early and very small have risen, but this improved survival rate is accompanied by increased risk of severe brain damage (Rogers & Hintz, 2016), lower level of executive function, especially in working memory and planning (Burnett & others, 2018), and lower intelligence (Jaekel & others, 2019).

One study revealed that very preterm, low birth weight infants had abnormal axon development in their brains and impaired cognitive development at 9 years of age (Iwata & others, 2012). Low birth weight children are more likely than their normal birth weight counterparts to develop a learning disability, attention deficit hyperactivity disorder, autism spectrum disorder, or breathing problem such as asthma (Brinskma & others, 2017; Ng & others, 2017). In a recent national study of 6- to 11-year-old U.S. children, those born preterm had higher rates of developmental delay, intellectual disability, speech/language disorder, learning disability, and ADHD (Kelly & Li, 2019). In another recent study, very preterm born children had lower achievement scores in math, reading, and spelling than their full-term counterparts in elementary school (Twilhaar & others, 2018). Approximately 50 percent of all low birth weight children are enrolled in special education programs. And a study in four Asian countries revealed that very low birth weight infants had a much higher mortality rate than other neonates (Wariki & others, 2013).

Nurturing Low Birth Weight and Preterm Infants

Two increasingly used interventions in the neonatal intensive care unit (NICU) are kangaroo care and massage therapy. **Kangaroo care** involves skin-to-skin contact in which the baby, wearing only a diaper, is held upright against the parent's bare chest, much as a baby kangaroo is carried by its mother (Endo, Sampei, & Fukuda, 2021). Kangaroo care is typically practiced for two to three hours per day over an extended time in early infancy.

kangaroo care A way of holding a preterm infant so that there is skin-to-skin contact.

Why use kangaroo care with preterm infants? Preterm infants often have difficulty coordinating their breathing and heart rate, and the close physical contact with the parent provided

by kangaroo care can help stabilize the preterm infant's heartbeat, temperature, and breathing (Montealegre-Pomar & Charpak, 2021). Preterm infants who experience kangaroo care also gain more weight than their counterparts who are not given this care (Sharma, Murki, & Oleti, 2018). However, in a recent research review, this outcome for preterm or low birth weight infants depended on the duration of the kangaroo care (Charpak, Montealegre-Pomar, & Bohorquez, 2021). In this review, these infants held in maternal kangaroo care for 2 to 6 hours a day or more gained more weight than a control group who did not get kangaroo care; however, the weight gain effect disappeared for infants who received maternal kangaroo care for only 2 hours or less per day. Also, only infants who received maternal kangaroo care for 6 hours a day or more gain more length and head circumference. Recent research also revealed that kangaroo care decreased pain responses in preterm infants (Mooney-Leber & Brummelte, 2017). Also, in a longitudinal study, the nurturing positive effects of kangaroo care with preterm and low birth weight infants that were initially found for intelligence and home environment at 1 year of age were maintained 20 years later in emerging adults' reduced school absenteeism, reduced hyperactivity, lower aggressiveness, and better social skills (Charpak & others, 2017). Further, in a large-scale experimental study in India, low birth weight infants were randomly assigned to receive kangaroo care or standard care (Mazumder & others, 2019). The low birth weight infants who received kangaroo care had a higher survival rate in the first month of life as well as at 180 days after being born.

A new mother practicing kangaroo care. *What is kangaroo care?*
casenbina/iStockphoto

One U.S. survey found that mothers had a much more positive view of kangaroo care than did neonatal intensive care nurses and that the mothers were more likely to think it should be provided daily (Hendricks-Munoz & others, 2013). There is concern that kangaroo care is not used as often as it could be used in neonatal intensive care units (Coutts & others, 2021; Stadd & others, 2020). Increasingly, kangaroo care is recommended as standard practice for all newborns (Maniago, Almazan, & Albougami, 2020).

In addition to kangaroo care, another technique that supports the healthy development of preterm infants is massage therapy. In a recent study of preterm infants, those who were given massage therapy had a significant daily weight gain and greater bone mineral density than infants who received routine care (Elmoneim & others, 2021). To read further about research on massage therapy, see the *Connecting with Research* interlude.

BONDING

A special component of the parent-infant relationship is **bonding,** the formation of a connection, especially a physical bond, between parents and their newborn infant during the period shortly after birth. In the mid-twentieth century, U.S. hospitals seemed almost determined to deter bonding. Anesthesia given to the mother during delivery would make the mother drowsy, interfering with her ability to respond to and stimulate the newborn. Mothers and newborns were often separated shortly after delivery, and preterm infants were isolated from their mothers even more than full-term infants were. In recent decades, these practices have changed, but to some extent they are still followed in many hospitals.

Do these practices do any harm? Some physicians believe that during the "critical period" shortly after birth the parents and newborn need to form an emotional attachment as a foundation for optimal development in the years to come (Kennell, 2006; Kennell & McGrath, 1999). Although some research supports this bonding hypothesis (Klaus & Kennell, 1976), a body of research challenges the significance of the first few days of life as a critical period (Bakeman & Brown, 1980; Rode & others, 1981). Indeed, the extreme form of the bonding hypothesis—the insistence that the newborn *must* have close contact with the mother in the first few days of life to develop optimally—simply is not true.

Nevertheless, the weakness of the bonding hypothesis should not be used as an excuse to keep motivated mothers from interacting with their newborns. Such contact brings pleasure to many mothers and may dispel maternal anxiety about the baby's health and safety. In some cases—including preterm infants, adolescent mothers, and mothers from disadvantaged

How Are Preterm Infants Affected by Touch?

Tiffany Fields

Key Points:

- preterm infants
- massage therapy
- outcomes: weight gain, lower stress, and other positive developments

Many preterm infants experience less touch than full-term infants do because they are isolated in temperature-controlled incubators. Research by Tiffany Field and her colleagues (2001, 2007, 2016, 2017; Diego, Field, & Hernandez-Reif, 2008, 2014; Field, Diego, & Hernandez-Reif, 2008, 2011) has led to a surge of interest in the role that massage might play in improving developmental outcomes for preterm infants. In Field's first study in this area, massage therapy that consisted of firm stroking with the palms of the hands was given three times per day for 15-minute periods to preterm infants (Field & others, 1986). Infants who received massage therapy had 47 percent greater weight gain than infants who received standard medical treatment. The massaged infants also were more active and alert than preterm infants who were not massaged, and they performed better on developmental tests.

In later studies, Field (2016) demonstrated the benefits of massage therapy for infants who faced a variety of problems. For example, preterm infants exposed to cocaine in utero who received massage therapy gained weight and had higher scores on developmental tests than their counterparts who did not receive massage therapy (Field, 2001). In one study, preterm infants in a neonatal intensive care unit (NICU) were randomly assigned to a massage therapy group or a control group (Hernandez-Reif, Diego, & Field, 2007). For five consecutive days, the preterm infants in the massage group were given three 15-minute moderate-pressure massages.

FIGURE **16**
PRETERM INFANTS SHOW REDUCED STRESS BEHAVIORS AND ACTIVITY AFTER FIVE DAYS OF MASSAGE THERAPY

Behavioral observations of the following stress behaviors were made on the first and last days of the study: crying, grimacing, yawning, sneezing, jerky arm and leg movements, startles, and finger flaring. The various stress behaviors were summarized in a composite stress behavior index. As indicated in Figure 16, massage had a stress-reducing effect on the preterm infants, which is especially important because they encounter numerous stressors while they are hospitalized.

In a review of the use of massage therapy with preterm infants, Field and her colleagues (Field, 2010) concluded that the most consistent findings were two positive results: (1) increased weight gain and (2) discharge from the hospital three to six days earlier.

circumstances—early close contact is key to establishing a climate for improved interaction after the mother and infant leave the hospital.

Many hospitals now offer a *rooming-in* arrangement, in which the baby remains in the mother's room most of the time during its hospital stay. However, if parents choose not to use this rooming-in arrangement, the weight of the research suggests that this decision will not harm the infant emotionally (Lamb, 1994).

postpartum period The period after childbirth when the mother adjusts, both physically and psychologically, to the process of childbirth. This period lasts for about six weeks or until her body has completed its adjustment and returned to a near prepregnant state.

THE POSTPARTUM PERIOD

The weeks after childbirth present challenges for many new parents and their offspring. This is the **postpartum period,** the period after childbirth or delivery that lasts for about six weeks

or until the mother's body has completed its adjustment and has returned to a nearly prepregnant state. It is a time when the woman adjusts, both physically and psychologically, to the process of childbearing.

Physical Adjustments A woman's body makes numerous physical adjustments in the first days and weeks after childbirth (Fein & others, 2021). She may have a great deal of energy or feel exhausted and let down. Though these changes are normal, the fatigue can undermine the new mother's sense of well-being and confidence in her ability to cope with a new baby and a new family life (Stuebe & others, 2021).

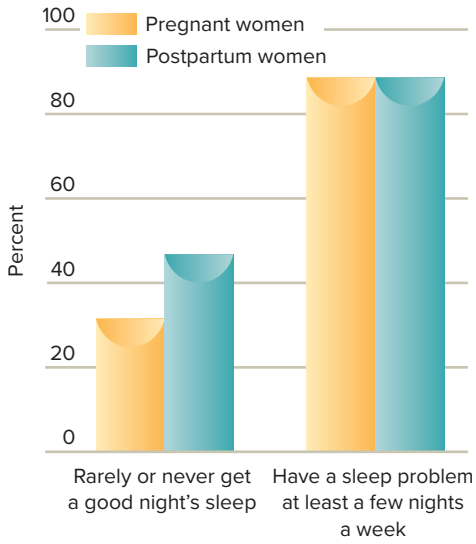

FIGURE 17
SLEEP DEPRIVATION IN PREGNANT AND POSTPARTUM WOMEN.

A concern is the loss of sleep that the primary caregiver experiences during the postpartum period (Obeysekare & others, 2020). In the 2007 Sleep in America survey, a substantial percentage of women reported loss of sleep during pregnancy and in the postpartum period (National Sleep Foundation, 2007) (see Figure 17). The loss of sleep can contribute to stress, marital conflict, and impaired decision making. However, research indicates that in the postpartum period, women who engage in light-to-moderate physical activity are less likely to experience poor sleep quality (Matenchuk & Davenport, 2021).

After delivery, the mother's body undergoes sudden and dramatic changes in hormone production. When the placenta is delivered, estrogen and progesterone levels drop steeply and remain low until the ovaries start producing hormones again.

Involution is the process by which the uterus returns to its prepregnant size five or six weeks after birth. Immediately following birth, the uterus weighs 2 to 3 pounds. By the end of five or six weeks, the uterus weighs 2 to 3 ounces. Nursing the baby helps contract the uterus at a rapid rate.

Emotional and Psychological Adjustments Emotional fluctuations are common for mothers in the postpartum period. For some women, emotional fluctuations decrease within several weeks after the delivery, but other women experience more long-lasting emotional swings (Desta & others, 2021; Mughal, Azhar, & Siddiqui, 2020).

As shown in Figure 18, about 70 percent of new mothers in the United States have what are called the *postpartum blues*. About two to three days after birth, they begin to feel depressed, anxious, and upset. These feelings may come and go for several months after the birth, often peaking about three to five days after birth. Even without treatment, these feelings usually go away after one or two weeks.

However, some women develop **postpartum depression,** which involves a major depressive episode that typically occurs about four weeks after delivery. Women with postpartum depression have such strong feelings of sadness, anxiety, or despair that for at least a two-week period they have trouble coping with their daily tasks. Without treatment, postpartum depression may become worse and last for many months. And many women with postpartum depression don't seek help. For example, one study found that 15 percent of the women surveyed had experienced postpartum depression symptoms but less than half had sought help (McGarry & others, 2009). Estimates indicate that 10 to 14 percent of new mothers experience postpartum depression. Also, researchers found

postpartum depression A major depressive episode that typically occurs about four weeks after delivery; women with this condition have such strong feelings of sadness, anxiety, or despair that they have trouble coping with daily tasks during the postpartum period.

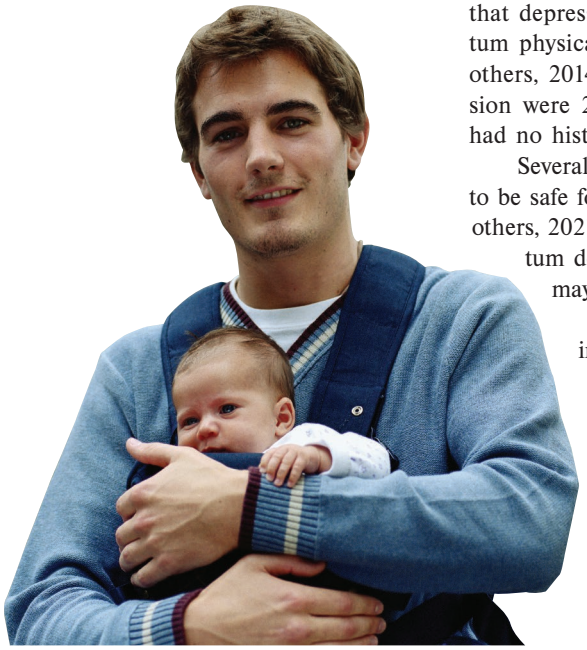
FIGURE 18
POSTPARTUM BLUES AND POSTPARTUM DEPRESSION AMONG U.S. WOMEN. Some health professionals refer to the postpartum period as the "fourth trimester." Though the time span of the postpartum period does not necessarily cover three months, the term "fourth trimester" suggests continuity and the importance of the first several months after birth for the mother.



The postpartum period is a time of considerable adjustment and adaptation for both the mother and the father. Fathers can provide an important support system for mothers, especially in helping mothers care for young infants. *What kinds of tasks might the father of a newborn do to support the mother?*
Howard Grey/Photodisc/Getty Images

that depression during pregnancy, a history of physical abuse, migrant status, and postpartum physical complications were major risk factors for postpartum depression (Gaillard & others, 2014). And another recent study revealed that women who had a history of depression were 20 times more likely to develop postpartum depression than were women who had no history of depression (Silverman & others, 2017).

Several antidepressant drugs are effective in treating postpartum depression and appear to be safe for breast-feeding women and their infants (Burval, Kerns, & Reed, 2020; Chow & others, 2021). Psychotherapy, especially cognitive therapy, also is effective for treating postpartum depression in many women (Liu & Yang, 2021). Also, engaging in regular exercise may help to relieve postpartum depression (Gobinath & others, 2018).

A mother's postpartum depression affects the way she interacts with her infant (Choe & others, 2020). A research review concluded that the interaction difficulties of depressed mothers and their infants occur across cultures and socioeconomic status groups, comprising reduced sensitivity of the mothers and decreased responsiveness on the part of infants (Field, 2010). In a one study, postpartum depression was associated with an increase in 4-month-old infants' injuries caused by neglect (Yamaoka, Fujiwara, & Tamiya, 2016).

Fathers also undergo considerable adjustment during the postpartum period, even when they work away from home all day (Howarth & Swain, 2020). When the mother develops postpartum depression, many fathers also experience depressed feelings (Sundstrom Poromaa & others, 2017). Many fathers feel that the baby comes first and gets all of the mother's attention; some feel that they have been replaced by the baby. In a recent meta-analysis, the prevalence of postpartum depression in fathers was 9 percent within the first month after birth and 8 percent 1 to 3 months after birth (Rao & others, 2020). A recent Japanese study found that 11.2 percent of fathers had depressive symptoms at one month following delivery (Nishigori & others, 2020). In another recent study, fathers with postpartum depression had lower levels of responsiveness, mood, and sensitivity when interacting with their infants (Koch & others, 2019).

The father's support and caring can influence whether the mother develops postpartum depression (Kumar, Oliffe, & Kelly, 2018). One study revealed that higher support by fathers was related to a lower incidence of postpartum depression in women (Smith & Howard, 2008).

Review *Connect* Reflect

LG5 Summarize how birth takes place and describe the nature of the postpartum period.

Review

- What are the three main stages of birth? What are some examples of different birth strategies?
- What is the transition from fetus to newborn like?
- What are the outcomes for children if they are born preterm or with a low birth weight?
- What is bonding? How is it linked to child outcomes?
- What are some characteristics of the postpartum period?

Connect

- Compare and contrast what you learned about kangaroo care and breast feeding of preterm infants with what you learned about bonding and breast feeding when the mother is suffering from postpartum depression.

Reflect *Your Own Personal Journey of Life*

- If you are a female, which birth strategy would you prefer? Why? If you are a male, how involved would you want to be in helping your partner through pregnancy and the birth of your baby?

Biological Beginnings

1 The Evolutionary Perspective

LG1 Discuss the evolutionary perspective on life-span development.

Natural Selection and Adaptive Behavior

- Natural selection is the process by which those individuals of a species that are best adapted to their environment are more likely to survive and reproduce.
- Darwin proposed that natural selection fuels evolution. In evolutionary theory, adaptive behavior is behavior that promotes the organism's survival in a natural habitat.

Evolutionary Psychology

- Evolutionary psychology holds that adaptation, reproduction, and "survival of the fittest" are important in shaping behavior. Ideas proposed by evolutionary developmental psychologists include the view that an extended childhood period is needed for humans to develop a large brain and learn the complexity of social communities.
- According to Baltes, the benefits resulting from evolutionary selection decrease with age, mainly because of a decline in reproductive fitness. At the same time, cultural needs increase. Like other theoretical approaches to development, evolutionary psychology has limitations. Bandura rejects "one-sided evolutionism" and argues for a bidirectional link between biology and environment.

2 Genetic Foundations of Development

LG2 Describe what genes are and how they influence human development.

The Collaborative Gene

- Short segments of DNA constitute genes, the units of hereditary information that help cells to reproduce and manufacture proteins. Genes act collaboratively, not independently.

Genes and Chromosomes

- Genes are passed on to new cells when chromosomes are duplicated during the processes of mitosis and meiosis, which are two ways in which new cells are formed.
- When an egg and a sperm unite in the fertilization process, the resulting zygote contains the genes from the chromosomes in the father's sperm and the mother's egg. Despite this transmission of genes from generation to generation, variability is created in several ways, including the exchange of chromosomal segments during meiosis, mutations, and the distinction between a genotype and a phenotype.

Genetic Principles

- Genetic principles include those involving dominant-recessive genes, sex-linked genes, genetic imprinting, and polygenic inheritance.

Chromosomal and Gene-Linked Abnormalities

- Chromosomal abnormalities produce Down syndrome, which is caused by the presence of an extra copy of chromosome 21. Other sex-linked chromosomal abnormalities include Klinefelter syndrome, fragile X syndrome, Turner syndrome, and XYY syndrome.
- Gene-linked abnormalities involve absent or harmful genes. Gene-linked disorders include phenylketonuria (PKU) and sickle-cell anemia.

3 Heredity and Environment Interaction: The Nature-Nurture Debate

LG3 Explain some of the ways that heredity and environment interact to produce individual differences in development.

Behavior Genetics

- Behavior genetics is the field that seeks to discover the influence of heredity and environment on individual differences in human traits and development.
- Methods used by behavior geneticists include twin studies and adoption studies.

Heredity-Environment Correlations

- In Scarr's heredity-environment correlations perspective, heredity may influence the types of environments that children experience. She describes three genotype-environment correlations: passive, evocative, and active (niche-picking). Scarr notes that the relative importance of these three genotype-environment correlations changes as children develop.

The Epigenetic View and Gene × Environment (G×E) Interaction

- The epigenetic view emphasizes that development is the result of an ongoing, bidirectional interchange between heredity and environment.
- Gene × environment (G × E) interaction involves the interaction of a specific measured variation in DNA and a specific measured aspect of the environment.

Conclusions About Heredity-Environment Interaction

- Complex behaviors have some genetic loading that gives people a propensity for a particular developmental trajectory. However, actual development also requires an environment, and that environment is complex.
- The interaction of heredity and environment is extensive. Much remains to be discovered about the specific ways that heredity and environment interact to influence development.

4 Prenatal Development

LG4 Characterize the course of prenatal development and its hazards.

The Course of Prenatal Development

- Prenatal development is divided into three periods: germinal (conception until 10 to 14 days later), which ends when the zygote (a fertilized egg) attaches to the uterine wall; embryonic (two to eight weeks after conception), during which the embryo differentiates into three layers, life-support systems develop, and organ systems begin to form (organogenesis); and fetal (lasting from two months after conception until about nine months, or when the infant is born), a period during which organ systems mature to the point at which life can be sustained outside the womb.
- By the time babies are born they have approximately 100 billion neurons, or nerve cells. The nervous system begins with the formation of a neural tube at 18 to 24 days after conception.
- Neurogenesis, proliferation, and migration are three processes that characterize brain development in the prenatal period. The basic architecture of the brain is formed in the first two trimesters of prenatal development.

Prenatal Diagnostic Tests

- Amniocentesis, ultrasound sonography, fetal MRI, chorionic villus sampling, maternal blood screening, and cell-free fetal DNA in maternal blood are used to determine whether a fetus is developing normally. The sex of the fetus can be determined as early as seven weeks into pregnancy.

Hazards to Prenatal Development

- A teratogen is any agent that can potentially cause a birth defect or negatively alter cognitive and behavioral outcomes. The dose, time of exposure, and genetic susceptibility influence the severity of the damage to an unborn child and the type of defect that occurs.
- Prescription drugs that can be harmful include antibiotics, some depressants, certain hormones, and acne medication (isotretinoin); nonprescription drugs that can be harmful include diet pills and aspirin. The psychoactive drugs caffeine, alcohol, nicotine, cocaine, marijuana, and synthetic opioids as well as opiate-related pain killers are potentially harmful to offspring. Cigarette smoking by pregnant women also has serious adverse effects on prenatal and child development (such as low birth weight).
- Problems may also result if a pregnant woman has rubella (German measles), syphilis, genital herpes, or AIDS. A developing fetus depends entirely on its mother for nutrition, and it may be harmed if the mother is malnourished, is overweight, or has a diet deficient in folic acid.
- High anxiety and stress in the mother are linked with less than optimal prenatal and birth outcomes.
- Maternal age can negatively affect the offspring's development if the mother is an adolescent or if she is 35 years of age or older.
- Radiation is a potential environmental hazard. Paternal factors also can affect the developing fetus.

Prenatal Care

- Prenatal care programs provide information about teratogens and other prenatal hazards. In addition, various medical conditions are screened for and medical care is given in a defined schedule of visits. Prenatal classes often give information on nutrition, sexuality during pregnancy, and types of birth.

5 Birth and the Postpartum Period

LG5 Summarize how birth takes place and describe the nature of the postpartum period.

The Birth Process

- Childbirth occurs in three stages. Childbirth strategies involve the childbirth setting and attendants. Methods of delivery include medicated, natural and prepared, and cesarean. An increasing number of nonmedicated techniques, such as waterbirth, are being used to reduce childbirth pain.

The Transition from Fetus to Newborn

- Being born involves considerable stress for the baby, but the baby is well prepared and adapted to handle the stress. For many years, the Apgar Scale has been used to assess the newborn's health.

Low Birth Weight and Preterm Infants

- Low birth weight infants weigh less than 5 pounds, and they may be preterm or small for date.
- Although most low birth weight infants are normal and healthy, as a group they have more health and developmental problems than infants of normal birth weight.
- Kangaroo care and massage therapy have been shown to provide benefits to preterm infants.

Bonding

- Bonding is the formation of a close connection, especially a physical bond between parents and the newborn shortly after birth. Early bonding has not been found to be critical in the development of a competent infant.

The Postpartum Period

- The postpartum period lasts from childbirth until about six weeks after the delivery or until the mother's body has completed its adjustment to a nonpregnant state. The development of postpartum depression is a concern during this period.

preview

Think about how much you have changed physically and will continue to change as you age. We come into this life as small beings. But we grow very rapidly in infancy, more slowly in childhood, rapidly during puberty, and then slowly. Eventually we decline, but many older adults remain physically robust. In this chapter, we explore changes in body growth, the brain, and sleep across the life span. We also examine longevity, evaluate some fascinating theories about why we age, and explore both physical and physiological aspects of development.

1 Body Growth and Change

LG1 Discuss major changes in the body through the life span.

- Patterns of Growth
- Height and Weight in Infancy and Childhood
- Puberty
- Early Adulthood
- Middle Adulthood
- Late Adulthood

In life's long journey, we go through many bodily changes. We grow up, we grow out, we shrink. The very visible changes in height and weight are accompanied by less visible ones in bones, lungs, and every other organ of the body. These changes influence how we think about ourselves, how other people think about us, and what we are capable of thinking, doing, and feeling. Are there strict timelines for these changes? Are they set in our genes? Let's begin by studying some basic patterns of growth and then trace bodily changes from the time we are infants through the time we are older adults.

PATTERNS OF GROWTH

Two key patterns of growth are the cephalocaudal and proximodistal patterns. The **cephalocaudal pattern** is the sequence in which the fastest growth in the human body occurs at the top, with the head. Physical growth in size, weight, and feature differentiation gradually works its way down from the top to the bottom (for example, neck, shoulders, middle trunk, and so on). This same pattern occurs in the head area, because the top parts of the head—the eyes and brain—grow faster than the lower parts, such as the jaw. During prenatal development and early infancy, the head constitutes an extraordinarily large proportion of the total body (see Figure 1).

In most cases, sensory and motor development proceeds according to the cephalocaudal pattern. For example, infants see objects before they can control their torso, and they can use their hands long before they can crawl or walk. However, one study contradicted the cephalocaudal pattern by finding that infants reached for toys with their feet before using their hands (Galloway & Thelen, 2004). In this study, infants on average first contacted the toy with their feet when they were 12 weeks old and with their hands when they were 16 weeks old. Thus, contrary to long-standing beliefs, early leg movements can be precisely controlled, some aspects of development that involve reaching do not involve lengthy practice, and early motor behaviors don't always develop in a strictly cephalocaudal pattern.

The **proximodistal pattern** is the growth sequence that starts at the center of the body and moves toward the extremities. An example is the early maturation of muscular control of the trunk and arms, compared with that of the hands and fingers. Further, infants use the whole hand as a unit before they can control several fingers.

An important point about growth is that it often is not smooth and continuous but rather is episodic, occurring in spurts (Adolph & Hoch, 2021; Rachwani, Hoch, & Adolph, 2021). In infancy, growth spurts may occur in a single day and alternate with long time frames characterized by little or no growth for days and weeks (Lampl, 2018, 2021). In two analyses, infants grew seven-tenths of an inch in length in a single day (Lampl, 1993) and their head circumference increased by three-tenths of an inch (Caino & others, 2010).

cephalocaudal pattern The sequence in which the fastest growth occurs at the top of the body—the head—with physical growth in size, weight, and feature differentiation gradually working from top to bottom.

proximodistal pattern The sequence in which growth starts at the center of the body and moves toward the extremities.

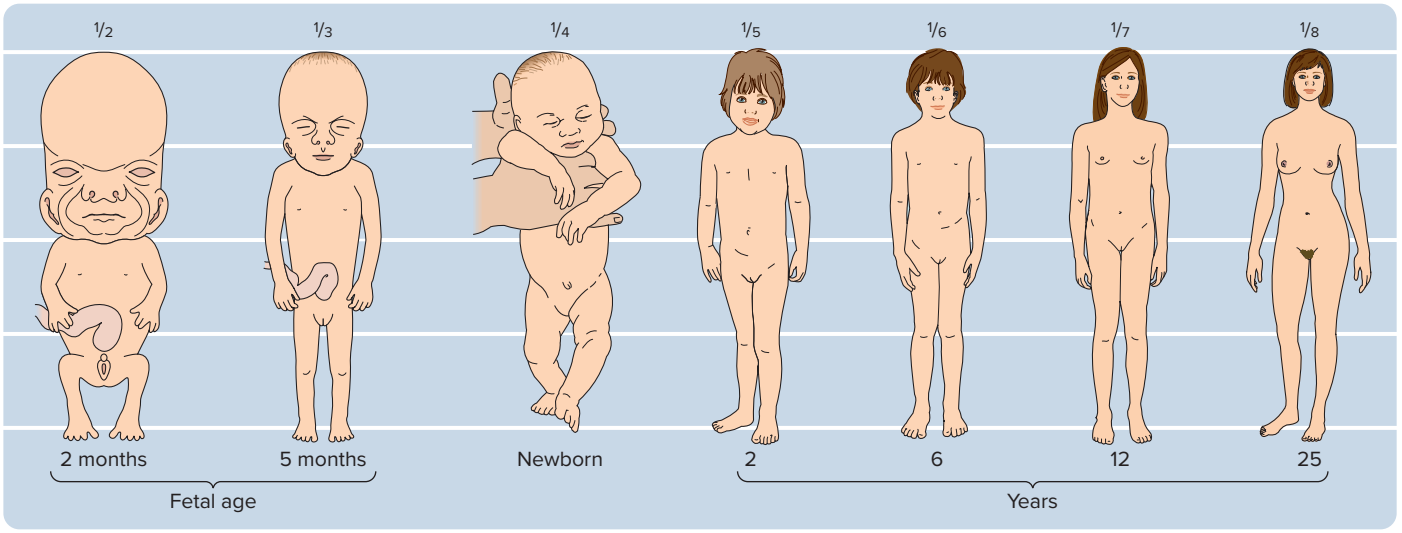

FIGURE **1**

CHANGES IN PROPORTIONS OF THE HUMAN BODY DURING GROWTH. As individuals develop from infancy through adulthood, one of the most noticeable physical changes is that the head becomes smaller in relation to the rest of the body. The fractions listed refer to head size as a proportion of total body length at different ages.

HEIGHT AND WEIGHT IN INFANCY AND CHILDHOOD

Height and weight increase rapidly in infancy, then take a slower course during childhood.

Infancy The average North American newborn is 20 inches long and weighs 7½ pounds. Ninety-five percent of full-term newborns are 18 to 22 inches long and weigh between 5½ and 10 pounds.

In the first several days of life, most newborns lose 5 to 7 percent of their body weight. Once infants adjust to sucking, swallowing, and digesting, they grow rapidly, gaining an average of 5 to 6 ounces per week during the first month. Typically, they have doubled their birth weight by the age of 4 months and have nearly tripled it by their first birthday. Infants grow about ¾ inch per month during the first year, increasing their birth length by about 40 percent by their first birthday.

Infants' rate of growth slows considerably in the second year of life (Hockenberry, Rogers, & Wilson, 2021). By 2 years of age, infants weigh approximately 26 to 32 pounds, having gained a quarter to half a pound per month during the second year; at age 2 they have reached about one-fifth of their adult weight. The average 2-year-old is 32 to 35 inches tall, which is nearly one-half of adult height.

The bodies of 5-year-olds and 2-year-olds are different from one another. The 5-year-old not only is taller and heavier, but also has a longer trunk and legs than the 2-year-old. *What might be some other physical differences between 2- and 5-year-olds?*
Michael Hitoshi/Digital Vision/Getty Images

Early Childhood What is the overall growth rate in early childhood? As the preschool child grows older, the percentage of increase in height and weight decreases with each additional year (Hay & others, 2021). Girls are only slightly smaller and lighter than boys during these years. Both boys and girls slim down as the trunks of their bodies lengthen. Although their heads are still somewhat large for their bodies, by the end of the preschool years most children have lost their top-heavy look. Body fat also shows a slow, steady decline during the preschool years. Girls have more fatty tissue than boys; boys have more muscle tissue (McMahon & Stryjewski, 2012).

Growth patterns vary individually (Glasper, Richardson, & Randall, 2021). Think back to your preschool years. This was probably the first time you noticed that some children were taller than you, some shorter; some were fatter, some thinner; some were stronger, some weaker. Much of the variation is due to heredity, but environmental experiences are also involved (Edwards & Coyne, 2020). A review of the height and weight of children around the world concluded that two important contributors to height differences are ethnic origin and nutrition (Meredith, 1978).

Why are some children unusually short? The culprits are congenital factors (genetic or prenatal problems), growth hormone deficiency, a physical problem that develops in childhood, maternal smoking during pregnancy, or an emotional difficulty (Polidori & others, 2020). A study of children born small for gestational age or short in stature revealed that five years of growth hormone treatment in childhood was linked to an increase to near-average height (Ross & others, 2015). Also, a recent meta-analysis found that recombinant growth hormone replacement therapy had a positive effect on metabolic changes in children with growth hormone deficiency (Yuan & others, 2021).

What characterizes children's physical growth in middle and late childhood?
RubberBall Productions/Getty Images

Middle and Late Childhood The period of middle and late childhood involves slow, consistent growth (Edwards & Coyne, 2020). This is a period of calm before the rapid growth spurt of adolescence.

During the elementary school years, children grow an average of 2 to 3 inches a year. At the age of 8, the average girl and the average boy are 4 feet 2 inches tall. During middle and late childhood, children gain about 5 to 7 pounds a year. The average 8-year-old girl and the average 8-year-old boy weigh 56 pounds. The weight increase is due mainly to increases in the size of the skeletal and muscular systems as well as the size of some body organs. Muscle mass and strength gradually increase as "baby fat" decreases in middle and late childhood (Hay & others, 2021).

Changes in proportions are among the most pronounced physical changes in middle and late childhood. Head circumference, waist circumference, and leg length decrease in relation to body height (Hockenberry, Rogers, & Wilson, 2021).

PUBERTY

Puberty is a brain-neuroendocrine process occurring primarily in early adolescence that provides stimulation for the rapid physical changes that take place during this period of development (Pfeifer & Allen, 2021; Sanfilippo & others, 2020). In this section, we explore a number of puberty's physical changes and its psychological accompaniments.

Sexual Maturation, Height, and Weight Think back to the onset of your puberty. Of the striking changes that were taking place in your body, what was the first to occur? Researchers have found that male pubertal characteristics typically develop in this order: increase in penis and testicle size, appearance of straight pubic hair, minor voice change, first ejaculation (which usually occurs through masturbation or a wet dream), appearance of curly pubic hair, onset of maximum growth in height and weight, growth of hair in armpits, more detectable voice changes, and, finally, growth of facial hair.

What is the order of appearance of physical changes in females? First, for most girls, their breasts enlarge or pubic hair appears. Later, hair appears in the armpits. As these changes occur, the female grows in height and her hips become wider than her shoulders.

Menarche—a girl's first menstruation—comes rather late in the pubertal cycle. Initially, her menstrual cycles may be highly irregular. For the first several years, she may not ovulate every menstrual cycle; some girls do not ovulate at all until a year or two after menstruation begins.

Marked weight gains coincide with the onset of puberty. During early adolescence, girls tend to outweigh boys, but by about age 14 boys begin to surpass girls. Similarly, at the beginning of the adolescent period, girls tend to be as tall as or taller than boys of their age, but by the end of the middle school years most boys have caught up or, in many cases, surpassed girls in height.

As indicated in Figure 2, the growth spurt occurs approximately two years earlier for girls than for boys. The mean age at the beginning of the growth spurt in girls is 9; for boys, it is 11. The peak rate of pubertal change occurs at 11½ years for girls and 13½ years for boys. During their growth spurt, girls increase in height about 3½ inches per year, boys about 4 inches.

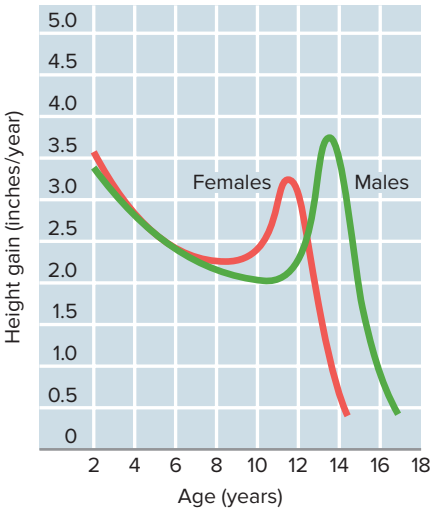

FIGURE 2

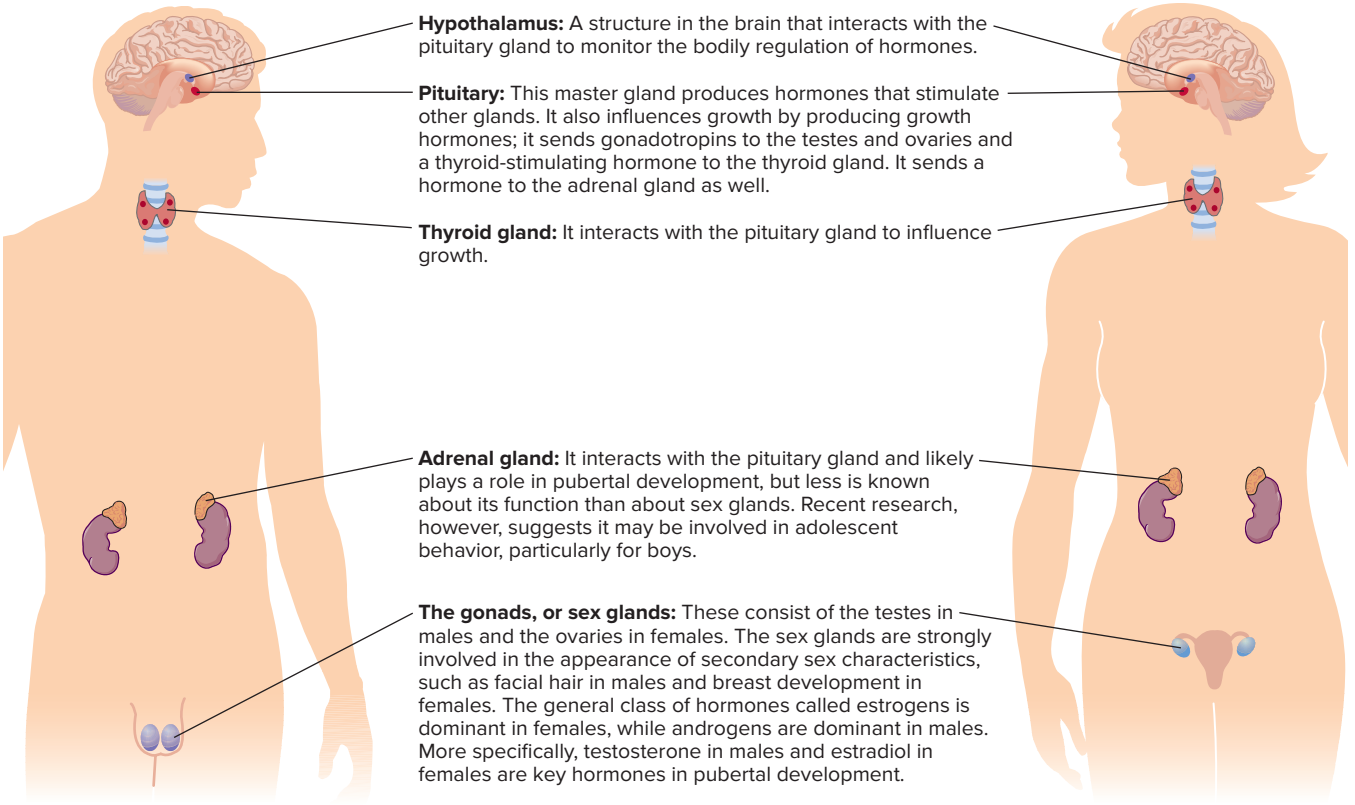
PUBERTAL GROWTH SPURT. On average, the peak of the growth spurt during puberty occurs two years earlier for girls (11½) than for boys (13½). *How are hormones related to the growth spurt and to the difference between the average height of adolescent boys and that of girls?*
Source: J. M. Tanner et al., "Standards from Birth to Maturity for Height, Weight, Height Velocity: British Children in 1965" in *Archives of Diseases in Childhood*, 41(219), pp. 454–471, 1966.

puberty A brain-neuroendocrine process occurring primarily in early adolescence that provides stimulation for the rapid physical changes that occur during this period of development.

menarche A girl's first menstrual period.



Hypothalamus: A structure in the brain that interacts with the pituitary gland to monitor the bodily regulation of hormones.
Pituitary: This master gland produces hormones that stimulate other glands. It also influences growth by producing growth hormones; it sends gonadotropins to the testes and ovaries and a thyroid-stimulating hormone to the thyroid gland. It sends a hormone to the adrenal gland as well.
Thyroid gland: It interacts with the pituitary gland to influence growth.
Adrenal gland: It interacts with the pituitary gland and likely plays a role in pubertal development, but less is known about its function than about sex glands. Recent research, however, suggests it may be involved in adolescent behavior, particularly for boys.
The gonads, or sex glands: These consist of the testes in males and the ovaries in females. The sex glands are strongly involved in the appearance of secondary sex characteristics, such as facial hair in males and breast development in females. The general class of hormones called estrogens is dominant in females, while androgens are dominant in males. More specifically, testosterone in males and estradiol in females are key hormones in pubertal development.

FIGURE **3**

THE MAJOR ENDOCRINE GLANDS INVOLVED IN PUBERTAL CHANGE.

developmental **connection**

Sexuality

Early sexual experience is one of a number of risk factors in adolescent development. Connect to "Gender and Sexuality."

hormones Powerful chemical substances secreted by the endocrine glands and carried through the body by the bloodstream.

hypothalamus A structure in the brain that is involved with eating and sexual behavior.

pituitary gland An important endocrine gland that controls growth and regulates the activity of other glands.

gonads The sex glands, which are the testes in males and the ovaries in females.

gonadotropins Hormones that stimulate the testes or ovaries.

testosterone A hormone associated in boys with the development of the genitals, increased height, and voice changes.

estradiol A hormone associated in girls with breast, uterine, and skeletal development.

Hormonal Changes Behind the first whisker in boys and the widening of hips in girls is a flood of **hormones,** powerful chemical substances secreted by the endocrine glands and carried through the body by the bloodstream (Frederiksen & others, 2020). The endocrine system's role in puberty involves the interaction of the hypothalamus, the pituitary gland, and the gonads (see Figure 3). The **hypothalamus,** a structure in the brain, is involved with eating and sexual behavior. The **pituitary gland,** an important endocrine gland, controls growth and regulates other glands; among these, the **gonads**—the testes in males, the ovaries in females—are especially important in giving rise to pubertal changes in the body.

How do the gonads, or sex glands, work? The pituitary gland sends a signal via **gonadotropins** (hormones that stimulate the testes or ovaries) to the appropriate gland to manufacture hormones. These hormones give rise to such changes as the production of sperm in males and menstruation and the release of eggs from the ovaries in females (Rey, 2021). The pituitary gland, through interaction with the hypothalamus, detects when the optimal level of hormones is reached and maintains it with additional gonadotropin secretion (Naule, Malone, & Kaiser, 2021). Not only does the pituitary gland release gonadotropins that stimulate the testes and ovaries, but through interaction with the hypothalamus the pituitary gland also secretes hormones that either directly lead to growth and skeletal maturation or produce growth effects through interaction with the thyroid gland, located at the base of the throat.

The concentrations of certain hormones increase dramatically during adolescence (Spaziani & others, 2021). The concentrations of two key hormones increase in puberty, and the changes are very different in boys and girls:

- **Testosterone** is a hormone associated in boys with the development of genitals, increased height, and deepening of the voice.
- **Estradiol** is a type of estrogen associated in girls with breast, uterine, and skeletal development.

In one study, testosterone levels increased eighteenfold in boys but only twofold in girls during puberty; estradiol increased eightfold in girls but only twofold in boys (Nottelmann & others, 1987). Thus, both testosterone and estradiol are present in the hormonal makeup of both boys and girls, but testosterone dominates in male pubertal development, estradiol in

female pubertal development (Ding & others, 2018). A study of 9- to 17-year-old boys found that testosterone levels peaked at 17 years of age (Khairullah & others, 2014).

The same influx of hormones that grows hair on a male's chest and increases the fatty tissue in a female's breasts may also contribute to psychological development in adolescence (Pfeifer & Allen, 2021). For example, in a recent study of adolescent boys, higher testosterone levels were linked to lower delay of gratification (Laube, Lorenz, & van den Bos, 2019). And in a recent study of early adolescent boys in Japan, a lower level of testosterone was associated with social withdrawal (Hayashi & others, 2020).

Hormonal effects by themselves do not account for adolescent psychological development (Cicek & others, 2018). For example, in one study, social factors were much better predictors of young adolescent girls' depression and anger than hormonal factors (Brooks-Gunn & Warren, 1989). Behavior and moods also can affect hormones. Stress, eating patterns, exercise, sexual activity, tension, and depression can activate or suppress various aspects of the hormonal system. In sum, the hormone-behavior link is complex (Susman & Dorn, 2013).

Timing and Variations in Puberty In the United States—where children mature up to a year earlier than children in European countries—the average age of menarche has declined significantly since the mid-nineteenth century. Also, recent studies in Korea and Japan (Cole & Mori, 2017), China (Song & others, 2016), Saudi Arabia (Al Alwan & others, 2017), and Portugal (Queiroga & others, 2020) found that pubertal onset has been occurring earlier in recent years. In addition, a recent study in Taiwan revealed that the average age of menarche had declined by 0.43 years per decade in the past 30 years (Chow & others, 2021). And a recent research review of 30 studies in different countries around the world concluded that the age at which breast development began in girls (called thelarche) had declined by almost 3 months per decade from 1977 to 2013 (Eckert-Lind & others, 2021). Fortunately, however, we are unlikely to see pubescent toddlers, since what has happened in the past century is likely the result of improved nutrition and health, and the rate of decline in age of onset of puberty has slowed considerably in the last several decades.

Is age of pubertal onset linked to how tall boys and girls will be toward the end of adolescence? A study found that for girls, earlier onset of menarche, breast development, and growth spurt were linked to shorter height at 18 years of age; however, for boys, earlier age of growth spurt and slower progression through puberty were associated with being taller at 18 years of age (Yousefi & others, 2013).

Why do the changes of puberty occur when they do, and how can variations in their timing be explained? The basic genetic program for puberty is wired into the species (Lardone & others, 2020). However, nutrition, health, family stress, and other environmental factors also affect puberty's timing (Calcaterra & others, 2021). Weight also is linked to pubertal onset (Pereira & others, 2021). Recent research revealed that obesity was associated with earlier pubertal onset (Busch & others, 2020). Also, a recent study found that child sexual abuse was linked to earlier pubertal onset (Noll & others, 2017).

For most boys, the pubertal sequence may begin as early as age 10 or as late as 13½, and it may end as early as age 13 or as late as 17. Thus, the normal range is wide enough that, given two boys of the same chronological age, one might complete the pubertal sequence before the other one has begun it. For girls, menarche is considered within the normal range if it takes place between the ages of 9 and 15.

Psychological Accompaniments of Puberty What are some links between puberty and psychological characteristics? How do early and late maturation influence adolescents' psychological development?

Body Image One psychological aspect of puberty is certain for both boys and girls: Adolescents are preoccupied with their bodies (McCullough, Pieloch, & Marks, 2020; Miranda & others, 2021). At this age you may have looked in the mirror on a daily, and sometimes even hourly, basis to see if you could detect anything different about your changing body. Preoccupation with one's body image is strong throughout adolescence but is especially acute during puberty, a time when adolescents are more dissatisfied with their bodies than in late adolescence.

Gender Differences Gender differences characterize adolescents' perceptions of their bodies (Cabaco & others, 2021; Housseini & Padhy, 2020). For example, in a recent U.S. study

Adolescents show a strong preoccupation with their changing bodies and develop images of what their bodies are like. *Why might adolescent males have more positive body images than adolescent females?*
Ali Johnson Photography/Getty Images

of young adolescents, boys had a more positive body image than girls (Morin & others, 2017). Girls tend to have more negative body images, which to some extent may be due to media portrayals of the attractiveness of being thin while the percentage of girls' body fat is increasing during puberty (Calugi & Dalle Grave, 2019). Also, in a recent Chinese study of adolescents, girls were more dissatisfied with their appearance than boys were, but boys were more dissatisfied with their sexual organs (Zhang & others, 2020). And another study found that both boys' and girls' body images became more positive as they moved from the beginning to the end of adolescence (Holsen, Carlson Jones, & Skogbrott Birkeland, 2012).

Recent dramatic increases in adolescents' use of the Internet and social media have been accompanied by concerns about negative body images (Choukas-Bradley & others, 2020). n a recent study, higher social media use was linked to more negative body images among adolescents, more so for girls than boys (Kelly & others, 2019). In addition, a recent study of young adolescents indicated that girls had a more negative body image when they identified with an ideal social media portrayal (for example, stating that they want their body to look like the models they see on social media) (Rodgers & others, 2020). Further, a recent study of 11- to 14-year-olds indicated that those who had negative body images because of the influence of social media had higher rates of depressive symptoms, online social anxiety, difficulty making new friends, and social isolation (Charmaraman & others, 2021). In the same study, those who followed celebrities checked social media more often and were more likely to have depressive symptoms and online social anxiety. And in a recent study of U.S. college women, more time spent on Facebook was related to more frequent body and weight comparisons with other women, more attention to the physical appearance of others, and more negative feelings about their own bodies (Eckler, Kalyango, & Paasch, 2017).

Early and Late Maturation Did you enter puberty early, late, or on time? When adolescents mature earlier or later than their peers, they may have different experiences and perceive themselves differently (Hoyt & others, 2020). One study found that in the early high school years, late-maturing boys had a more negative body image than early-maturing boys (de Guzman & Nishina, 2014). Similarly, in the Berkeley Longitudinal Study conducted more than half a century ago, early-maturing boys perceived themselves more positively and had more successful peer relations than did late-maturing boys (Jones, 1965). The findings for early-maturing girls were similar but not as strong as for boys. When the late-maturing boys were in their thirties, however, they had developed a more positive identity than the early-maturing boys had (Peskin, 1967). Perhaps the late-maturing boys had had more time to explore life's options, or perhaps the early-maturing boys continued to focus on their physical status instead of paying attention to career development and achievement.

An increasing number of researchers have found that early maturation increases girls' vulnerability to a number of problems (Black & Rofey, 2018; Hamilton & others, 2014). Early-maturing girls are more likely to smoke, drink, be depressed, have an eating disorder, struggle for earlier independence from their parents, and have older friends. Their bodies are likely to elicit responses from males that lead to earlier dating and earlier sexual experiences (Pomerantz & others, 2017). One study found that early maturation predicted a stable higher level of depression for adolescent girls (Rudolph & others, 2014). Further, researchers have found that early-maturing girls tend to have sexual intercourse earlier and have more unstable sexual relationships (Moore, Harden, & Mendle, 2014), and are at increased risk for physical and verbal abuse in dating (Chen, Rothman, & Jaffee, 2017). Also, early-maturing girls are more likely to drop out of high school and to cohabit and marry at younger ages (Cavanagh, 2009). And researchers found that early-maturing girls had higher rates of depression and antisocial behavior as middle-aged adults, mainly because their difficulties began in adolescence and did not lessen over time (Mendle, Ryan, & McKone, 2018).

What are some outcomes of early and late maturation in adolescence?
Fuse/Corbis/Getty Images

Apparently as a result of their social and cognitive immaturity, combined with early physical development, early-maturing girls are easily lured into problem behaviors, not recognizing how these behaviors might affect their development. Thus, early-maturing adolescents, especially girls, require earlier risk education efforts

related to sexual development, risky behaviors, relationships, and Internet safety than their on-time peers (Susman & Dorn, 2013).

In sum, early maturation often has more favorable outcomes for boys than for girls, especially in early adolescence. However, late maturation may be more favorable for boys, especially in terms of identity and career development. Research increasingly has found that early-maturing girls are vulnerable to a number of problems.

EARLY ADULTHOOD

After the dramatic physical changes of puberty, the years of early adulthood might seem to be an uneventful time in the life cycle. Physical changes during these years may be subtle, but they do continue.

Height remains rather constant during early adulthood. Peak functioning of the body's joints usually occurs in the twenties. Many individuals also reach a peak of muscle tone and strength in their late teens and twenties (Candow & Chilibeck, 2005). However, these attributes may begin to decline in the thirties. Sagging chins and protruding abdomens may also appear for the first time. Muscles start to have less elasticity, and aches may appear in places not felt before.

Most of us reach our peak levels of physical performance before the age of 30, often between the ages of 19 and 26. This peak of physical performance occurs not only for the average young adult, but for outstanding athletes as well. Different types of athletes, however, reach their peak performances at different ages. Most swimmers and gymnasts peak in their late teens. Golfers and marathon runners tend to peak in their late twenties. In other areas of athletics, peak performance often occurs in the early to mid-twenties. However, in recent years, some highly conditioned athletes—such as Serena Williams (tennis) and Tom Brady (football)—have stretched the upper age limits of award-winning performances.

MIDDLE ADULTHOOD

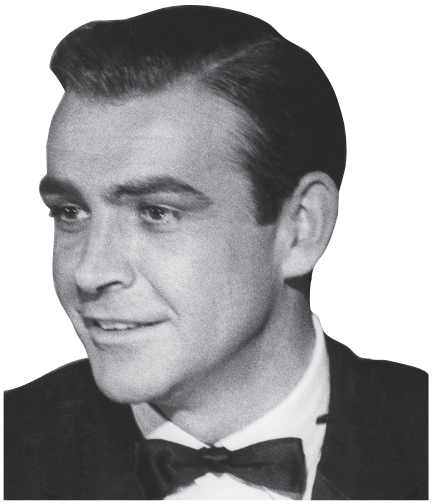
Like the changes of early adulthood, midlife physical changes are usually gradual. Although everyone experiences some physical change due to aging in middle adulthood, the rates of aging vary considerably from one individual to another. Genetic makeup and lifestyle factors play important roles in whether and when chronic diseases will appear (Vecellio & others, 2021). Middle age is a window through which we can glimpse later life while there is still time to engage in preventive behaviors and influence the course of aging (Liu & Lachman, 2020).

Physical Appearance Individuals lose height in middle age, and many gain weight (Blake, 2020). On average, from 30 to 50 years of age, men lose about half an inch in height, then lose another half-inch from 50 to 70 years of age (Hoyer & Roodin, 2009). The height loss for women can be as much as 2 inches from 25 to 75 years of age. Note that there are large variations in the extent to which individuals become shorter with aging. The decrease in height is due to bone loss in the vertebrae. On average, body fat accounts for about 10 percent of body weight in adolescence; it makes up 20 percent or more in middle age.

Noticeable signs of aging usually are apparent by the forties or fifties. The skin begins to wrinkle and sag because of a loss of fat and collagen in underlying tissues (Sifaki & others, 2020; Ye & others, 2021). Small, localized areas of pigmentation in the skin produce aging spots, especially in areas that are exposed to sunlight, such as the hands and face. The hair thins and grays because of a lower replacement rate and a decline in melanin production (O'Sullivan & others, 2021).

Since a youthful appearance is valued in many cultures, many Americans strive to make themselves look younger. Undergoing cosmetic surgery, dyeing hair, purchasing wigs, enrolling in weight reduction programs, participating in exercise regimens, and taking heavy doses of vitamins are common in middle age. Baby boomers have shown a strong interest in plastic surgery and Botox, which may reflect their desire to take control of the aging process (Abelsson & Willman, 2021; Dong & Stenmark, 2021).

Regarding weight gain in middle age, in 2017–2018 the prevalence of obesity in middle-aged adults (44.8 percent) was higher than in younger adults (40 percent) and older adults (42.8 percent) (Hales & others, 2020). Middle-aged men had a higher obesity rate (46.4 percent) than middle-aged women (43.3 percent). Being overweight is a critical health problem for middle-aged



The late actor Sean Connery as a young adult in his twenties (*top*) and as a middle-aged adult in his fifties (*bottom*). *What are some of the most outwardly noticeable signs of aging in middle adulthood?*

Middle age is when your age starts to show around your middle.

—Bob Hope
20th Century Comedian

adults and increases their risk of developing a number of other health problems, including hypertension and diabetes (Itoh & others, 2020; Liu & others, 2021). For individuals who are 30 percent overweight, the probability of dying in middle adulthood increases by about 40 percent.

Strength, Joints, and Bones The term *sarcopenia* refers to age-related loss of lean muscle mass and strength (Wiedmer & others, 2021). After age 50, muscle loss occurs at a rate of approximately 1 to 2 percent per year. A loss of strength especially occurs in the back and legs. A recent study found that smoking and diabetes were risk factors for accelerated loss of muscle mass in middle-aged women (Lee & Choi, 2019).

Recently, researchers began using the term *sarcopenic obesity* in reference to individuals who have sarcopenia and are obese (El Bizri & Batsis, 2020). A recent meta-analysis concluded that older adults with sarcopenic obesity are at increased risk of adverse musculoskeletal outcomes such as falls and fractures than individuals with sarcopenia, obesity, or neither condition (Gandham & others, 2021). Also, in another study sarcopenic obesity was associated with a 24 percent increase in risk for all-cause mortality, with a higher risk for men than women (Tian & Xu, 2016). A research review concluded that weight management and resistance training were the best strategies for slowing down sarcopenia (Rolland & others, 2011).

Maximum bone density occurs by the mid- to late thirties. From that point on, there is a progressive loss of bone. The rate of bone loss begins slowly but accelerates during the fifties (Locquet & others, 2018). Women's rate of bone loss is about twice that of men. By the end of midlife, bones break more easily and heal more slowly (de Villiers, 2018). A recent study found that greater intake of fruits and vegetables was linked to increased bone density in middle-aged and older adults (Qiu & others, 2017).

Cardiovascular System Cardiovascular disease increases considerably in middle age (Mosley & others, 2020). The level of cholesterol in the blood increases through the adult years (Zhou & others, 2020). Cholesterol comes in two forms: LDL (low-density lipoprotein) and HDL (high-density lipoprotein). LDL is often referred to as "bad" cholesterol because when the level of LDL is too high, it sticks to the lining of blood vessels, a condition that can lead to arteriosclerosis (hardening of the arteries). HDL is often referred to as "good" cholesterol because when it is high and LDL is low, the risk of cardiovascular disease decreases. One study revealed that a higher level of HDL was linked to a higher probability of being alive at 85 years of age (Rahilly-Tierney & others, 2011). In middle age, cholesterol begins to accumulate on the artery walls, thickening them. The result is an increased risk of cardiovascular disease (Kocar, Rezen, & Rozman, 2021).

Blood pressure, too, usually rises in the forties and fifties, and high blood pressure (hypertension) is linked with an increased rate of mortality as well as lower cognitive functioning (Mrowka, 2017). In a recent study of individuals 55 years of age and younger, those with hypertension had lower memory test scores (Teles de Menezes & others, 2021). Also, one study revealed that hypertension in middle age was linked to an increased risk of cognitive impairment in late adulthood (23 years later) (Virta & others, 2013). At menopause, a woman's blood pressure rises sharply and usually remains above that of a man through life's later years (Taler, 2009).

The health benefits of cholesterol-lowering and hypertension-lowering drugs are a major factor in improving the health of many middle-aged adults and increasing their life expectancy (Rosenson, Hegele, & Koenig, 2019). Regular exercise and healthy eating habits also have considerable benefits in preventing cardiovascular disease (Schiff, 2021). In a recent study of middle-aged adults, higher cardiorespiratory fitness predicted lower rates of cardiovascular disease (Swainson, Ingle, & Carroll, 2019). As reflected in the research we have just described, the American Heart Association has proposed Life's Simple 7—a list of actions people can take to improve their cardiovascular health. The seven actions are: (1) manage blood pressure, (2) control cholesterol, (3) reduce blood sugar, (4) get active, (5) eat better, (6) lose weight, and (7) quit smoking. In a recent study, optimal Life's Simple 7 at middle age was linked to better cardiovascular health recovery following a heart attack later in life (Mok & others, 2018). In a recent study, of Life's Simple 7, most of these actions were linked to greater longevity (van Oort & others, 2021).

Lungs There is little change in lung capacity through most of middle adulthood. However, at about the age of 55, the proteins in lung tissue become less elastic. This change, combined with a gradual stiffening of the chest wall, decreases the lungs' capacity to shuttle oxygen from the air people breathe to the blood in their veins.

For smokers, however, the picture is different and bleaker (Roden, 2021). The lung capacity of smokers drops precipitously in middle age. When people quit smoking their lung capacity improves, although not to the level of individuals who have never smoked (Williams, 1995). Physical activity also promotes lung health. One study found that lung cancer diagnoses were 68 percent lower among men who were the most physically fit compared with those who were the least physically fit (Lakoski & others, 2013). And in a recent study, lower body mass index, less exercise, frequent alcohol drinking, and a meat-based diet were risk factors for lung cancer among never-smoking women (Ko & others, 2020).

Sexuality **Climacteric** is the midlife transition when fertility declines. **Menopause** is the time in middle age, usually in the late forties or early fifties, when a woman has not had a menstrual period for a full year. The average age at which women have their last period is 51 (Mayo Clinic, 2021). However, there is large variation in the age at which menopause occurs—from 39 to 59 years of age. A recent Norwegian study of more than 300,000 women found that late menopause was associated with an increased risk of breast cancer (Gottschalk & others, 2020). In this study, the mean age of menopause had increased 2½ years in recent decades to 52.7 years in Norway.

During menopause, production of estrogen by the ovaries declines dramatically, and this decline produces uncomfortable symptoms in some women—"hot flashes," nausea, fatigue, and rapid heartbeat, for example (Stuenkel, 2021). However, cross-cultural studies reveal wide variations in the menopause experience (Sievert & Obermeyer, 2012). For example, hot flashes are uncommon in Mayan women (Beyene, 1986), and Asian women report fewer hot flashes than women in Western societies (Payer, 1991). It is difficult to determine the extent to which these cross-cultural variations are due to genetic, dietary, reproductive, or cultural factors.

Menopause is not the negative experience for most women that it was once thought to be. One study in Taiwan found no significant effect of menopausal transition on women's quality of life (Cheng & others, 2007). However, the loss of fertility is an important marker for women (Lumsden & Sassarini, 2019).

Do men go through anything like the menopause that women experience? In other words, is there a male menopause? During middle adulthood, most men do not lose their capacity to father children, although there usually is a modest decline in their sexual hormone level and their frequency of sexual activity (Abootalebi & others, 2020). Testosterone production begins to decline about 1 percent a year during middle adulthood, and this decline can reduce sexual drive (Hyde & others, 2012). Sperm count usually shows a slow decline, but men do not lose their fertility altogether.

We will have more to say about the climacteric and the sexual attitudes and behaviors of middle-aged women and men in the chapter on "Gender and Sexuality."

Researchers have found that almost 50 percent of Canadian and American menopausal women have occasional hot flashes, but only one in seven Japanese women do (Lock, 1998). *What factors might account for these variations?*
BLOOMimage/Getty Images

LATE ADULTHOOD

Late adulthood brings an increased risk of physical disability, but there is considerable variability in rates of decline in functioning. Let's explore changes in physical appearance and the cardiovascular system in older adults.

Physical Appearance The changes in physical appearance that take place in middle adulthood become more pronounced in late adulthood. Most noticeable are facial wrinkles and age spots. Our weight usually drops after we reach 60 years of age, likely because we lose muscle, which also gives our bodies a more "sagging" look. Recent research indicates that obesity is linked to mobility limitation in older adults (Adair, Duazo, & Borja, 2018). The good news is that exercise and weight lifting can help slow the decrease in muscle mass, improve physical appearance, increase mobility, and reduce frailty (Brahms & others, 2021). In one study, at-risk overweight and obese older adults lost significant weight and improved their mobility considerably by participating in a community-based weight reduction program (Rejeski & others, 2017).

climacteric The midlife transition during which fertility declines.

menopause The time in middle age, usually in the late forties or early fifties, when a woman's menstrual periods have ceased for one year.

Sarah Kagan, Geriatric Nurse

Sarah Kagan is a professor of nursing at the University of Pennsylvania School of Nursing. She provides nursing consultation to patients, their families, nurses, and physicians regarding the complex needs of older adults related to their hospitalization. She also consults on research and the management of patients who have head and neck cancers. Kagan teaches in the undergraduate nursing program, where she directs a course on "Nursing Care in the Older Adult." In 2003, she was awarded a MacArthur Fellowship for her work in the field of nursing.

In Kagan's own words:

I'm lucky to be doing what I love—caring for older adults and families—and learning from them so that I can share this knowledge and develop or investigate better ways of caring. My special interests in the care of older adults who have cancer allow me the intimate privilege of being with patients at the best and worst times of their lives. That intimacy acts as a beacon—it reminds me of the value I and nursing as a profession contribute to society and the rewards offered in return (Kagan, 2008, p. 1).

Sarah Kagan with a patient.
Jacqueline Larma/AP Photo

For more information about what geriatric nurses do, see the Careers in Life-Span Development appendix.

Circulatory System Significant changes also take place in the circulatory system during late adulthood (Cohle & Miller, 2021). In older adults, 64 percent of men and 69 percent of women 65 to 74 years of age have hypertension (high blood pressure) (Centers for Disease Control and Prevention, 2018). Today, most experts on aging recommend that consistent blood pressure above 120/80 should be treated to reduce the risk of heart attack, stroke, or kidney disease. A rise in blood pressure with age can be linked to illness, obesity, stiffening of blood vessels, stress, or lack of exercise (Wahab & others, 2021). The longer any of these factors persist, the higher the individual's blood pressure gets. Various drugs, a healthy diet, and exercise can reduce the risk of cardiovascular disease in older adults (Jefferson, Demasi, & Doshi, 2020). In a recent study of adults age 65 and older, a Mediterranean diet lowered their risk of cardiovascular problems (Nowson & others, 2018).

Geriatric nurses can be especially helpful to older adults who experience acute or chronic illness. To read about the work of one geriatric nurse, see the *Connecting with Careers* profile.

2 The Brain LG2 Describe how the brain changes through the life span.

The Neuroconstructivist View | Brain Physiology | Infancy | Childhood | Adolescence | Adulthood and Aging

Until recently, little was known for certain about how the brain changes as we grow and age. Today, dramatic progress is being made in understanding these changes (Richards & Conte, 2021). The study of age-related changes in the brain is one of the most exciting frontiers in science (Barbey, Karama, & Haier, 2021). As we saw in "Biological Beginnings," remarkable changes occur in the brain during prenatal development. Here we consider the changes in the brain from infancy through late adulthood. Before exploring these developmental changes, let's first explore what is meant by the neuroconstructivist view and examine some key structures of the brain and see how they function.

THE NEUROCONSTRUCTIVIST VIEW

Not long ago, scientists thought that our genes exclusively determine how our brains are "wired" and that the cells in the brain responsible for processing information just maturationally unfold with little or no input from environmental experiences. In that view, your genes provide the blueprint for your brain and you are essentially stuck with it. This view, however, has turned out to be wrong. Instead, researchers have found that the brain has plasticity and its development depends on context (Esteves & others, 2021).

The brain depends on experiences to determine how connections are made (Rachwani, Hoch, & Adolph, 2021). Before birth, it appears that genes mainly direct basic wiring patterns. Neurons grow and travel to distant places awaiting further instructions (Borsani & others, 2019). After birth, the inflowing stream of sights, sounds, smells, touches, language, and eye contact help shape the brain's neural connections.

Thus, the dogma of the unchanging brain has been discarded and researchers are mainly focused on context-induced plasticity of the brain over time (Peven, Stillman, & Erickson, 2020; Schmidt & others, 2021). The development of the brain mainly changes in a bottom-to-top sequence with sensory, appetitive (eating, drinking), sexual, sensation-seeking, and risk-taking brain linkages maturing first and higher-level brain linkages such as self-control, planning, and reasoning maturing later (Zelazo, 2013).

In the increasingly popular **neuroconstructivist view,** (a) biological processes (genes, for example) and environmental experiences (enriched or impoverished, for example) influence the brain's development; (b) the brain has plasticity and is context dependent; and (c) development of the brain is closely linked with cognitive development. These factors constrain or advance the construction of cognitive skills (Birle & others, 2021; Pinho, Marcut, & Fonseca, 2020). The neuroconstructivist view emphasizes the importance of interactions between experiences and gene expression in the brain's development, much as the epigenetic view proposes (Baroncelli & Lunghi, 2021).

FIGURE 4

THE HUMAN BRAIN'S HEMISPHERES. The two hemispheres of the human brain are clearly seen in this photograph. It is a myth that the left hemisphere is the exclusive location of language and logical thinking or that the right hemisphere is the exclusive location of emotion and creative thinking.
IgorZD/Shutterstock

neuroconstructivist view Developmental perspective in which biological processes and environmental conditions influence the brain's development; the brain has plasticity and is context dependent; and cognitive development is closely linked with brain development.

BRAIN PHYSIOLOGY

The brain includes a number of major structures. The key components of these structures are *neurons*—nerve cells that handle information processing.

Structure and Function Looked at from above, the brain has two halves, or hemispheres—left and right (see Figure 4). The top portion of the brain, farthest from the spinal cord, is known as the forebrain. Its outer layer of cells, the cerebral cortex, covers it like a thin cap. The cerebral cortex is responsible for about 80 percent of the brain's volume and is critical in perception, thinking, language, and other important functions.

Each hemisphere of the cortex has four major areas, called lobes. Although the lobes usually work together, each has somewhat different primary functions (see Figure 5):

- *Frontal lobes* are involved in voluntary movement, thinking, personality, emotion, memory, sustained attention, and intentionality or purpose.
- *Occipital lobes* function in vision.

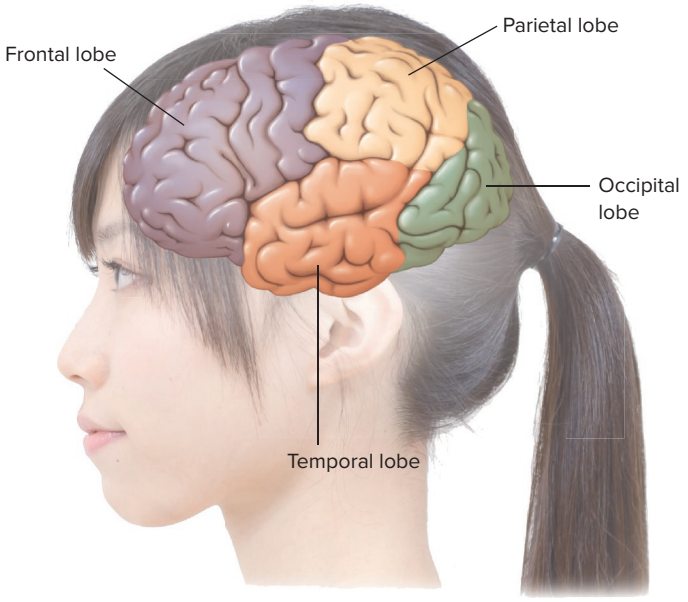

FIGURE 5

THE BRAIN'S FOUR LOBES. Shown here are the locations of the brain's four lobes: frontal, occipital, temporal, and parietal.
Takayuki/Shutterstock

- *Temporal lobes* have an active role in hearing, language processing, and memory.
- *Parietal lobes* play important roles in registering spatial location, focusing attention, and maintaining motor control.

Deeper in the brain, beneath the cortex, lie other key structures. These include the hypothalamus and the pituitary gland as well as the amygdala, which plays an important role in emotions, and the hippocampus, which is especially important in memory and emotion.

Neurons As we discussed earlier, neurons process information. Figure 6 shows some important parts of the neuron, including the axon and dendrites. Basically, an axon sends electrical signals away from the central part of the neuron. At tiny gaps called synapses, the axon communicates with the dendrites of other neurons, which then pass the signals on. The communication in the synapse occurs through the release of chemical substances known as *neurotransmitters* (De Deurwaerdere & Di Giovanni, 2021).

How complex are these neural connections? In a research analysis, it was estimated that each of the billions of neurons is connected to as many as 1,000 other neurons, producing neural networks with trillions of connections (de Haan, 2015).

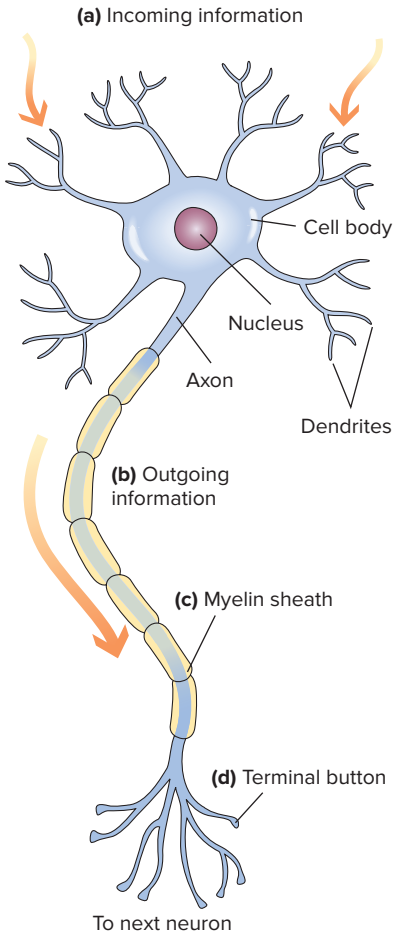

FIGURE 6

THE NEURON. (*a*) The dendrites of the cell body receive information from other neurons, muscles, or glands through the axon. (*b*) Axons transmit information away from the cell body. (*c*) A myelin sheath covers most axons and speeds information transmission. (*d*) As the axon ends, it branches out into terminal buttons.

As Figure 6 shows, most axons are covered by a myelin sheath, which is a layer of fat cells. Development of this sheath through a process called **myelination** helps impulses travel faster along the axon, increasing the speed and efficiency with which information travels from neuron to neuron (Muzio & Cascella, 2020; Wang & others, 2021). Myelination also is involved in providing energy to neurons and in facilitating communication (Moss & others, 2021; Shen & others, 2020).

To some extent, the type of information handled by neurons depends on whether they are in the left or the right hemisphere of the cortex (Othman & others, 2020). Speech and grammar, for example, depend on activity in the left hemisphere in most people; humor and the use of metaphors depend on activity in the right hemisphere (Veronelli & others, 2020). Recent research also indicates that attention (Bartolomeo & Seidel Malkinson, 2019) and emotion (Gainotti, 2019) are predominantly right-hemisphere activities. As an indication of the role played by left and right hemispheres in language development, recent brain-imaging research with 18- to 27-month-old infants documented that the attention function of the right frontal cortex played an important role in left-lateralized word processing (Bosseler & others, 2021). Further, recent MRI research demonstrated that both the right and left hemispheres are involved in the control and processing of emotions (Bajaj & Killgore, 2021).

The specialization of function in one hemisphere of the cerebral cortex or the other is called **lateralization.** However, most neuroscientists agree that complex functions such as reading or performing music involve both hemispheres. Labeling

myelination The process of encasing axons with a myelin sheath, thereby improving the speed and efficiency of information processing.

lateralization Specialization of function in one hemisphere or the other of the cerebral cortex.

people as "left-brained" because they are logical thinkers or "right-brained" because they are creative thinkers does not reflect the way the brain's hemispheres work. For the most part, complex thinking is the outcome of communication between the hemispheres of the brain.

The degree of lateralization may change as people develop through the life span. Let's now explore a number of age-related changes in the brain.

INFANCY

Brain development occurs extensively during the prenatal period. The brain's development is also substantial during infancy and later.

Conducting Research and Measuring the Infant's Brain Activity Among the researchers who are making strides in finding out more about the brain's development in infancy are the following individuals:

- Martha Ann Bell and her colleagues (Bell, 2020, 2022; Bell & Broomell, 2022; Bell, Diaz, & Liu, 2019; Bell, Phillips, & Bruce, 2022; Bell, Ross, & Patton, 2018; Blankenship, Broomell, & Bell, 2018; Cuevas & Bell, 2021), who are studying brain-behavior links, emotion regulation, temperament, inhibitory control, and the integration of cognition and emotion;
- Charles Nelson and his colleagues (Bick & Nelson, 2017; Nelson, 2007, 2013, 2020; Nelson, Fox, & Zeanah, 2014; Nelson & Gabard-Durnam, 2020), who are exploring various aspects of memory development, face recognition and facial emotion, and the role of early experience in influencing the course of brain development;
- Mark Johnson and his colleagues (Gui & others, 2020; Johnson, Senju, & Tomalski, 2015; Johnson & others, 2015, 2021; Jones & others, 2020; Kolesnik & others, 2019; Mercure & others, 2020; Piccardi & others, 2021), who are examining neuroconstructivist links between the brain, cognitive and perceptual processes, and environmental influences; studying the development of the prefrontal cortex and its function; and exploring early identification of autism, face processing, and the effects of early social experiences;
- John Richards and his colleagues (Bayet & others, 2021; Conte & others, 2020; O'Reilly & others, 2020; Porto & others, 2020; Reynolds & Richards, 2019; Richards, 2013; Richards & Conte, 2021), who are examining sustained attention, perception of TV programs, and eye movements.

FIGURE 7

MEASURING THE ACTIVITY IN AN INFANT'S BRAIN WITH AN ELECTROENCEPHALOGRAM (EEG). By attaching up to 128 electrodes to a baby's scalp, Charles Nelson and his colleagues have studied the brain activity involved in the infant's ability to recognize faces and remember.

Courtesy of Vanessa Vogel Farley

Researchers have been successful in using the electroencephalogram (EEG), a measure of the brain's electrical activity, to learn about the brain's development in infancy (Cuevas & Bell, 2021; Richards & Conte, 2021) (see Figure 7). For example, one study found that higher-quality mother-infant interaction early in infancy predicted higher-quality frontal lobe functioning that was assessed with EEG later in infancy (Bernier, Calkins, & Bell, 2016).

Researchers are continuing to explore the use of other techniques to assess infants' brain functioning. Recently Patricia Kuhl and her colleagues at the Institute for Learning and Brain Sciences at the University of Washington have been using magnetoencephalography, or MEG, brain-imaging machines to assess infants' brain activity. MEG maps brain activity by recording magnetic fields produced by electrical currents and is being used with infants to assess perceptual and cognitive activities such as vision, hearing, and language (Bosseler & others, 2021; Yoshimura & others, 2020) (see Figure 8). And researchers also are increasingly using functional near-infrared spectroscopy (fNIRS), which uses very low levels of near-infrared light to monitor changes in blood oxygen, to study infants' brain activity in many areas, such as face processing, perception, attention, and memory (Andersen & others, 2020). (See Figure 9.) Unlike fMRI,

FIGURE 8

MEASURING THE ACTIVITY OF AN INFANT'S BRAIN WITH MAGNETOENCEPHALOGRAPHY (MEG). This baby's brain activity is being assessed with a MEG brain-imaging device while the baby is listening to spoken words in a study at the Institute for Learning and Brain Sciences at the University of Washington. The infant sits under the machine and when he or she experiences a word, touch, sight, or emotion, the neurons working together in the infant's brain generate magnetic fields and MEG pinpoints the location of the fields in the brain.

Steve Gschmeissner/Science Source

which uses magnetic fields or electrical activity, fNIRS is portable and allows the infants to be assessed as they explore the world around them (Papadelis & Chen, 2020).

Changing Neurons At birth, the newborn's brain is about 25 percent of its adult weight. By the second birthday, the brain is about 75 percent of its adult weight. Two key developments during these first two years involve the myelin sheath (the layer of fat cells that speeds up movement of electrical impulses along the axons) and connections between dendrites.

Myelination, the process of encasing axons with a myelin sheath, begins prenatally and continues after birth (see Figure 10). As indicated earlier, myelination plays an especially important role in increasing the speed and efficiency of information traveling from neuron to neuron (Wang & others, 2021). Myelination for visual pathways occurs rapidly after birth, reaching completion in the first six months. Auditory myelination is not completed until 4 or 5 years of age. Some aspects of myelination continue into adolescence and even into emerging adulthood and possibly beyond (Kwon & others, 2020). Indeed, the most extensive changes in myelination in the frontal lobes occur during adolescence (Monahan & others, 2016).

Dramatic increases in dendrites and synapses (the tiny gaps between neurons across which neurotransmitters carry information) also characterize the development of the brain in the first two years of life (see Figure 11). Nearly twice as many of these connections are made as will ever be used (Huttenlocher & Dabholkar, 1997). The connections that are used become stronger and survive, while the unused ones are replaced by other pathways or disappear. In the language of neuroscience, these connections are "pruned" (Sugama & Kakinuma, 2021). Figure 12 vividly illustrates the growth and later pruning of synapses in the visual, auditory, and prefrontal cortex areas of the brain (Huttenlocher & Dabholkar, 1997). As shown in Figure 12, "blooming and pruning" vary considerably by brain region in humans (Gogtay & Thompson, 2010).

Changing Structures The areas of the brain do not mature uniformly (Richards & Conte, 2021). The frontal lobe is immature in the newborn. As neurons in the frontal lobe become myelinated and interconnected during the first year of life, infants develop an ability to regulate their physiological states (such as sleep) and gain more control over their reflexes. Cognitive skills that require deliberate thinking do not emerge until later (Bell & Garcia Meza, 2021). At about 2 months of age, the motor control centers of the brain develop to the point at which infants can suddenly reach out and grab a nearby object. At about 4 months, the neural connections necessary for depth perception begin to form. And at about 12 months, the brain's speech centers are poised to produce one of infancy's magical moments: when the infant utters its first word.

FIGURE 11

THE DEVELOPMENT OF DENDRITIC SPREADING. Note the increase in connectedness between neurons over the course of the first two years of life.

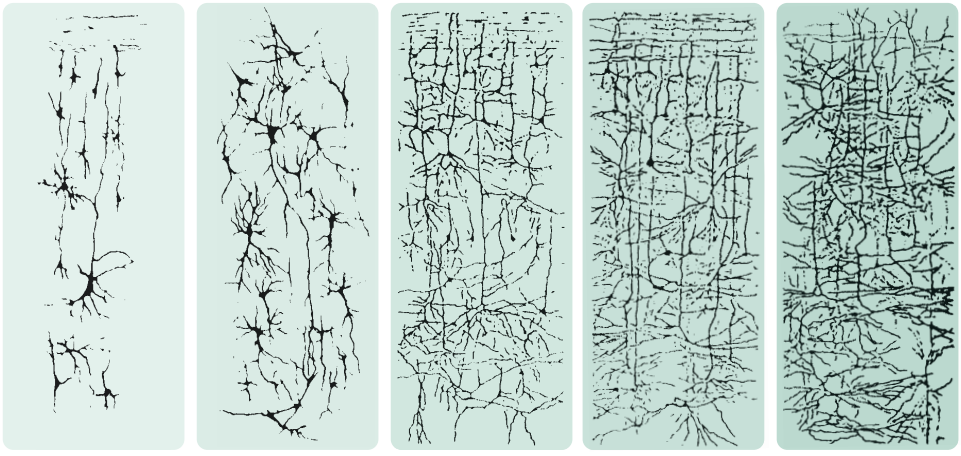

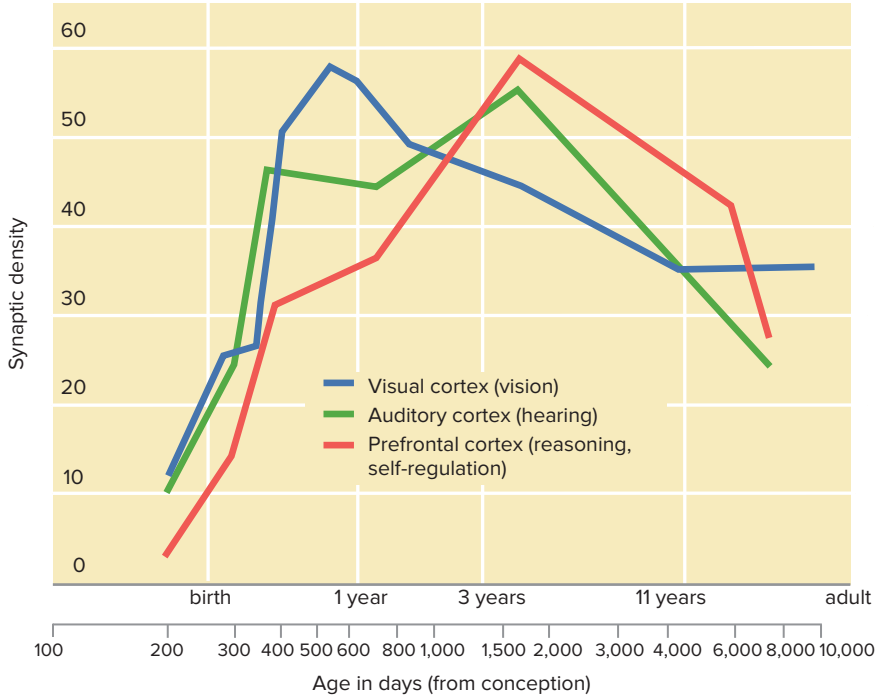

FIGURE 12

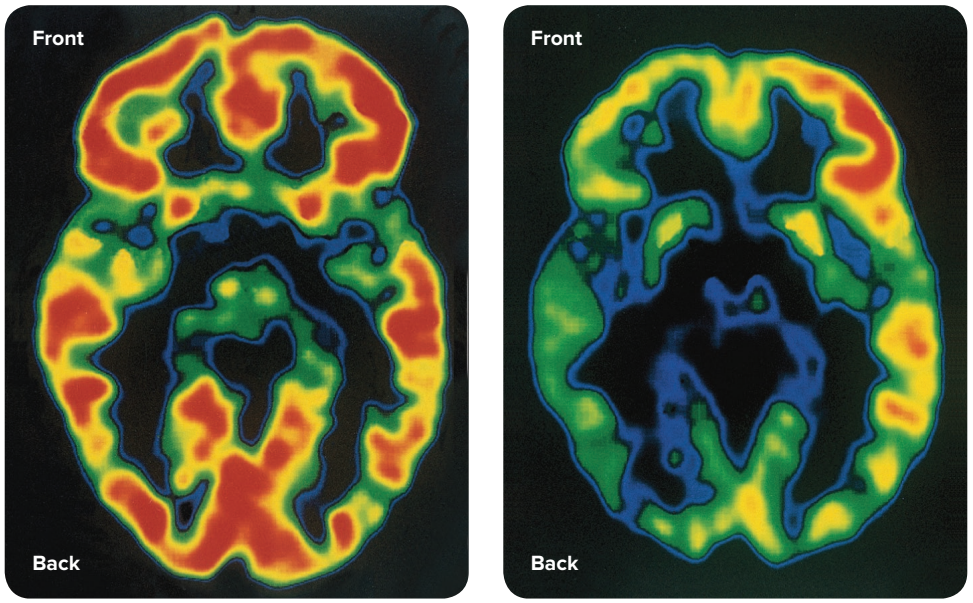
SYNAPTIC DENSITY IN THE HUMAN BRAIN FROM INFANCY TO ADULTHOOD. The graph shows the dramatic increase followed by pruning in synaptic density for three regions of the brain: visual cortex, auditory cortex, and prefrontal cortex. Synaptic density is believed to be an important indication of the extent of connectivity between neurons.



(a) (b)

FIGURE 13

EARLY DEPRIVATION AND BRAIN ACTIVITY. These two photographs are PET (positron emission tomography) scans—which use radioactive tracers to image and analyze blood flow and metabolic activity in the body's organs. These scans show the brains of (*a*) a normal child and (*b*) an institutionalized Romanian orphan who experienced substantial deprivation since birth. In PET scans, the highest to lowest brain activity is reflected in the colors of red, yellow, green, blue, and black, respectively. As can be seen, red and yellow show up to a much greater degree in the PET scan of the normal child than that of the deprived Romanian orphan.
Courtesy of Dr. Harry T. Chugani, Children's Hospital of Michigan

Early Experience and the Brain Research has shown that children who grow up in a deprived environment may have depressed brain activity (Nelson, Fox, & Zeanah, 2014; Wade & others, 2020). For example, children who grew up in the unresponsive and unstimulating environment of a Romanian orphanage showed considerably depressed brain activity compared with children who grew up in a normal environment. As shown in Figure 13, a child who grew

FIGURE **14**

PLASTICITY IN THE BRAIN'S HEMISPHERES. Michael Rehbein at 14 years of age. Following removal of the left hemisphere of Michael's brain because of uncontrollable seizures, his right hemisphere reorganized to take over the language functions normally carried out by corresponding areas in the left hemisphere of an intact brain.
Courtesy of The Rehbein Family

up in the unresponsive and unstimulating environment of a Romanian orphanage showed considerably depressed brain activity compared with a child raised in a normal environment. In a recent follow-up assessment at 16 years of age, however, the orphanage children who subsequently were placed in stable foster care showed improved brain functioning (Debnath & others, 2020).

Are the effects of deprived environments reversible? There is reason to think that at least to some degree and for some individuals the answer is yes (Dennis & others, 2014). The brain demonstrates both flexibility and resilience (Stark & others, 2020). Consider 14-year-old Michael Rehbein. At age 7, he began to experience uncontrollable seizures—as many as 400 a day. Doctors said the only solution was to remove the left hemisphere of his brain where the seizures were occurring. Recovery was slow, but his right hemisphere began to reorganize and take over functions that normally occur in the brain's left hemisphere, including speech (see Figure 14).

Neuroscientists note that what wires the brain—or rewires it, in the case of Michael Rehbein—is repeated experience. Each time a baby tries to touch an attractive object or gazes intently at a face, tiny bursts of electricity shoot through the brain, knitting together neurons into circuits. The results are some of the behavioral milestones we discuss in this and other chapters.

CHILDHOOD

The brain and other parts of the nervous system continue developing through childhood (Bell, 2022; Bell & Broomell, 2022). These changes enable children to plan their actions, to attend to stimuli more effectively, and to make considerable strides in language development.

During early childhood, the brain and head grow more rapidly than any other part of the body. Figure 15 shows how the growth curve for the head and brain advances more rapidly than the growth curve for height and weight. Some of the brain's increase in size is due to myelination and some is due to an increase in the number and size of dendrites. Some developmentalists conclude that myelination is important in the maturation of a number of abilities in children (Kwon & others, 2020). For example, myelination in the areas of the brain related to hand-eye coordination is not complete until about 4 years of age. Myelination in the areas of the brain related to focusing attention is not complete until the end of middle or late childhood.

The brain in early childhood is not growing as rapidly as it did in infancy, yet the anatomical changes in the child's brain between the ages of 3 and 15 are dramatic. By repeatedly obtaining brain scans of the same children for up to four years, scientists have found that children's brains experience rapid, distinct growth spurts (Gogtay & Thompson, 2010). The amount of brain material in some areas can nearly double in as little as one year, followed by a drastic loss of tissue as unneeded cells are purged and the brain continues to reorganize itself.

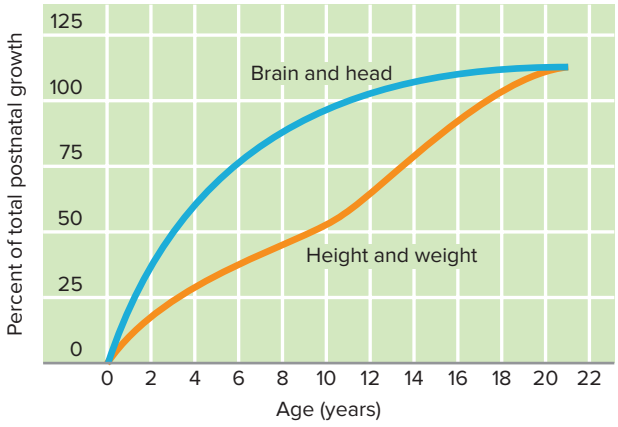


FIGURE **15**

GROWTH CURVES FOR THE HEAD AND BRAIN AND FOR HEIGHT AND WEIGHT. The more rapid growth of the brain and head can easily be seen. Height and weight advance more gradually over the first two decades of life.

The substantial increases in memory and rapid learning that characterize infants and young children are related to myelination and synaptic growth. In one study, young children with higher cognitive ability showed increased myelination by 3 years of age (Deoni & others, 2016).

These aspects of the brain's maturation, combined with opportunities to experience a widening world, contribute to children's emerging cognitive abilities. Consider a child who is learning to read and is asked by a teacher to read aloud to the class. Input from the child's eyes is transmitted to the child's brain, then passed through many brain systems, which translate (process) the patterns of black and white into codes for letters, words, and associations. The output occurs in the form of messages to the child's lips and tongue. The child's own gift of speech is possible because brain systems are organized in ways that permit language processing.

Recently, researchers have found that contextual factors such as poverty and parenting quality are linked to the development of the brain during childhood (Dufford, Kim, & Evans, 2020; Gard & others, 2021). In one study, children from the poorest homes had significant

maturational lags in their frontal and temporal lobes at 4 years of age, and these lags were associated with lower school readiness skills (Hair & others, 2015). In another study, higher levels of maternal sensitivity in early childhood were associated with higher total brain volume (Kok & others, 2015). Further, a recent study indicated that maltreatment risk and home adversity in infancy were linked to cortical delays and brain immaturity at 8 years of age (Bick & others, 2019). However, children assigned to an attachment and biobehavioral catchup intervention showed improved brain functioning. And in a longitudinal study, 11- to 18-year-olds who lived in poverty conditions had diminished brain functioning at 25 years of age (Brody & others, 2017). However, the adolescents from poverty backgrounds whose families participated in a supportive parenting intervention did not show this diminished brain functioning in adulthood.

Significant changes in various structures and regions of the brain continue to occur during middle and late childhood (Geng, Botdorf, & Riggins, 2021). In particular, the brain pathways and circuitry involving the **prefrontal cortex,** the highest level in the brain, continue to increase in middle and late childhood (Johnson, Riis, & Noble, 2016). The brain is hierarchically organized and mainly develops from the bottom up, with sensory areas reaching maturity before the higher-level association areas such as the prefrontal cortex.

In one study, researchers found decreases in diffusion and increases in focal activation in the prefrontal cortex between 7 and 30 years of age (Durston & others, 2006). The activation change was accompanied by increased efficiency in cognitive performance, especially in cognitive control, which involves flexible and effective control in a number of areas. These areas include controlling attention, reducing interfering thoughts, inhibiting motor actions, and being cognitively flexible in switching between competing choices (Aben & others, 2019).

Developmental neuroscientist Mark Johnson and his colleagues (Johnson, Grossmann, & Cohen-Kadosh, 2009) have proposed that the prefrontal cortex likely orchestrates the functions of many other brain regions during development. As part of this neural leadership and organizational role, the prefrontal cortex may provide an advantage to neural connections and networks that include the prefrontal cortex. In their view, the prefrontal cortex likely coordinates the best neural connections for solving a problem. Also, recent research indicates that emerging cognitive control during childhood is mainly supported by the development of distributed neural networks in which the prefrontal cortex is central (Chevalier & others, 2019). Further, a recent study found that 9- to 10-year-olds with a high body mass index had less cortical thickness, which was linked to a lower level of executive function (Laurent & others, 2020). And in another recent study, reduced amygdala-prefrontal connectivity occurred in children with autism spectrum disorder (Ibrahim & others, 2019).

developmental **connection**

Intelligence

Might some regions of the brain be more closely linked with children's intelligence than others? Connect to "Intelligence."

ADOLESCENCE

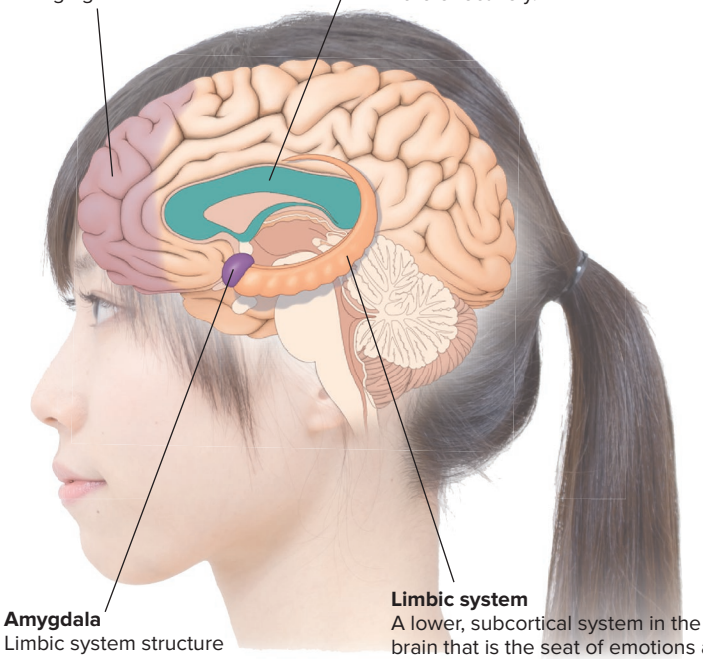
Until recently, little research has been conducted on developmental changes in the brain during adolescence. Although research in this area is still in its infancy, an increasing number of studies are under way (Modabbernia & others, 2021; Vasa & others, 2020). Scientists now note that the adolescent's brain is different from the child's brain, and that in adolescence the brain is still growing (Volkow & others, 2020). In a recent study of 9- to 23-year-olds, similar brain aging patterns were found for girls and boys, although the brain changes occurred approximately one year earlier in females (Brouwer & others, 2021).

Earlier we indicated that connections between neurons become "pruned" as children and adolescents develop. Because of this pruning, by the end of adolescence individuals have "fewer, more selective, more effective neuronal connections than they did as children" (Kuhn, 2009, p. 153). And this pruning indicates that the activities adolescents choose to engage in or not to engage in influence which neural connections will be strengthened and which will disappear.

Using fMRI brain scans, scientists have discovered that adolescents' brains undergo significant structural and connectivity changes (Andrews, Ahmed, & Blakemore, 2021; Garcia-Tabuenca & others, 2021). These structural changes occur in the corpus callosum, the prefrontal cortex, and the limbic system. The **corpus callosum** consists of fibers that connect the brain's left and right hemispheres. In adolescence, these fibers thicken, which improves information

prefrontal cortex The highest level of the frontal lobes that is involved in reasoning, decision making, and self-control.

corpus callosum A large bundle of axon fibers that connects the brain's left and right hemispheres.



Prefrontal cortex
This "judgment" region reins in intense emotions but doesn't finish developing until at least emerging adulthood.
Corpus callosum
These nerve fibers connect the brain's two hemispheres; they thicken in adolescence to process information more effectively.
Amygdala
Limbic system structure especially involved in emotion.
Limbic system
A lower, subcortical system in the brain that is the seat of emotions and experience of rewards. This system is almost completely developed in early adolescence.

Takayuki/Shutterstock

processing. A recent research indicated that the corpus callosum continues to thicken well into the third decade of life (Danielsen & others, 2020).

We described advances in the development of the prefrontal cortex—the highest level of the frontal lobes involved in reasoning, decision making, and self-control—earlier in this chapter. The prefrontal cortex doesn't finish maturing until the emerging adult years (18 to 25 years old) or later (Casey & others, 2019). At a lower, subcortical level, the **limbic system,** which is the seat of emotions and where rewards are experienced, matures much earlier than the prefrontal cortex and is almost completely developed by early adolescence (Casey & others, 2019). The limbic system structure that is especially involved in emotion is the **amygdala.** Figure 16 shows the locations of the corpus callosum, prefrontal cortex, and the limbic system.

With the onset of puberty, the levels of neurotransmitters change. For example, an increase in the neurotransmitter dopamine occurs in both the prefrontal cortex and the limbic system during adolescence (Ladouceur & others, 2019). Increases in dopamine have been linked to increased risk taking and the use of addictive drugs (Liu & McNally, 2021). Researchers have found that dopamine plays an important role in reward seeking during adolescence (Dubol & others, 2018).

Let's further consider the developmental disjunction between the early development of the limbic system and the later development of the prefrontal cortex. This disjunction may account for increased risk taking and other problem behaviors in adolescence. To read further about risk-taking behavior in adolescence, see the *Connecting Development to Life* interlude.

By the time individuals reach emerging adulthood, there are increased connections across brain areas. In a recent study, reduced connectivity between the brain's frontal lobes and amygdala during adolescence was linked to increased depression (Scheuer & others, 2017). And in another recent study, connectivity between the prefrontal cortex and hippocampus increased from adolescence to emerging and early adulthood, with this connectivity linked to improvement in higher-level cognition, especially in problem solving and planning (Calabro & others, 2020).

Many of the changes in the adolescent brain that have been described involve the rapidly emerging field of *developmental social neuroscience* (which involves connections between development, the brain, and socioemotional processes) (Andrews, Ahmed, & Blakemore, 2021; Forbes & others, 2021) and *developmental cognitive neuroscience* (which involves links between development, cognition, and neuroscience) (Cheng & others, 2021; Mercurio & others, 2020). For example, consider leading researcher Charles Nelson's (2003) view that, although adolescents are capable of very strong emotions, their prefrontal cortex hasn't adequately developed to the point at which they can control these passions. It is as if their brain doesn't have the brakes to slow down their emotions. Or consider this interpretation of the development of emotion and cognition in adolescents: "early activation of strong 'turbo-charged' feelings with a relatively un-skilled set of 'driving skills' or cognitive abilities to modulate strong emotions and motivations" (Dahl, 2004, p. 18). And in the view of leading expert Jay Giedd (2007), biology doesn't make teens rebellious or have purple hair and it does not mean that they are going to do drugs, but it increases their chances of doing such things.

Of course, a major issue is which comes first, biological changes in the brain or experiences that stimulate these changes (Tooley & others, 2020). Consider a study in which the prefrontal cortex thickened and more brain connections formed when adolescents resisted peer pressure (Paus & others, 2008). Scientists have yet to determine whether the brain changes come first or whether the brain changes are the result of experiences with peers, parents, and

Strategies for Helping Adolescents Reduce Their Risk-Taking Behavior

Beginning in early adolescence, individuals seek experiences that create high-intensity feelings (Murner-Lavanchy & others, 2020). Adolescents like intensity, excitement, and arousal (Freund, Schulenberg, & Maslowsky, 2021). They are drawn to music videos that shock and bombard the senses. Teenagers flock to horror and slasher movies. They dominate queues waiting to ride high-adrenaline rides at amusement parks. Adolescence is a time when sex, drugs, very loud music, and other high-stimulation experiences take on great appeal. It is a developmental period when an appetite for adventure, a predilection for risks, and desire for novelty and thrills seem to reach naturally high levels (Andrews & others, 2020). While these patterns of emotional changes are present to some degree in most adolescents, it is important to recognize the wide range of individual differences during this period of development (Dahl, 2004, p. 6).

The self-regulatory skills necessary to inhibit risk taking often don't develop fully until later in adolescence or emerging adulthood (LaSpada & others, 2020). And, as we just saw, this gap between the increase in risk-taking behavior and the delay in self-regulation is linked to brain development in the limbic system (involved in pleasure seeking and emotion) taking place earlier than development of the frontal lobes (involved in self-regulation) (Monahan & others, 2016).

It is important for parents, teachers, mentors, and other responsible adults to effectively monitor adolescents' behavior. In many cases, adults decrease their monitoring of adolescents too early, leaving them to cope with tempting situations alone or with friends and peers. When adolescents are in tempting and dangerous situations with minimal adult supervision, their inclination to engage in risk-taking behavior combined with their immature self-regulatory skills can make them vulnerable to a host of negative outcomes (Smout & others, 2020).

How might developmental changes in the brain be involved in adolescent risk taking? What are some strategies for reducing adolescent risk taking?
Image Source/Getty Images

What does the nature-nurture debate suggest about the influence of adults who monitor adolescents' lives?

others. Once again, we encounter the nature/nurture issue that is so prominent in an examination of development through the life span. Nonetheless, there is adequate evidence that environmental experiences make important contributions to the brain's development (Andrews, Ahmed, & Blakemore, 2021; Casey & others, 2019).

In closing this section on the development of the brain in adolescence, a further caution is in order. Much of the research on neuroscience and the development of the brain in adolescence is correlational in nature, and thus causal statements need to be scrutinized. This caution, of course, applies to any period in the human life span.

ADULTHOOD AND AGING

Changes in the brain continue during adulthood. Most of the research on the brains of adults, however, has focused on the aging brains of older adults. What are some of the general findings about the aging brain? How much plasticity and adaptability does it retain?

The Shrinking, Slowing Brain On average, the brain loses 5 to 10 percent of its weight between the ages of 20 and 90. Brain volume also decreases (Taubert & others, 2020). A study found a decrease in total brain volume and volume in key brain structures such as

the frontal lobes and hippocampus from 22 to 88 years of age (Sherwood & others, 2011). Another study found that the volume of the brain was 15 percent less in older adults than younger adults (Shan & others, 2005). Further, a recent study of older adults revealed that declines in memory functioning were linked to lower volumes of gray matter (which contains most of the brain's neuronal cell bodies) in the temporal lobe and hippocampus (Schneider & others, 2019). Also, recent analyses concluded that in healthy aging the decrease in brain volume is due mainly to shrinkage of neurons, lower numbers of synapses, reduced length and complexity of axons, and reduced tree-like branching in dendrites, but only to a minor extent attributable to neuron loss (Barter & Foster, 2020). In addition, in one study, higher global brain volume predicted lower mortality risk in a large population of stroke-free community-dwelling adults (Van Elderen & others, 2016). Of course, for individuals with disorders such as Alzheimer disease, significant neuron loss occurs (Adduru & others, 2020). And a recent study found that brain atrophy occurred less often in women than in men (Kirov & others, 2021).

Some areas of the brain shrink more than others (Squarzoni & others, 2018). The prefrontal cortex is one area that shrinks with aging, and research has linked this shrinkage with a decrease in working memory and other cognitive activities in older adults (Kronovsek & others, 2021; Larrabee, 2020). The sensory regions of the brain—such as the primary visual cortex, primary motor cortex, and somatosensory cortex—are less vulnerable to the aging process (Hromas & Bauer, 2020).

Changes in the corpus callosum, the bundle of fibers that connect the brain's two hemispheres, occur in late adulthood. In a recent study, the corpus callosum began to show protracted decline in the mid-to-late fifties, followed by further decline in older adults (Danielsen & others, 2020).

A general slowing of function in the brain and spinal cord begins in middle adulthood and accelerates in late adulthood (Salthouse, 2017). Both physical coordination and intellectual performance are affected. For example, after age 70, many adults no longer show a knee jerk reflex, and by age 90 most reflexes are much slower (Spence, 1989). The slowing of the brain can impair the performance of older adults on intelligence tests and various cognitive tasks, especially those that are timed (Lu & others, 2011).

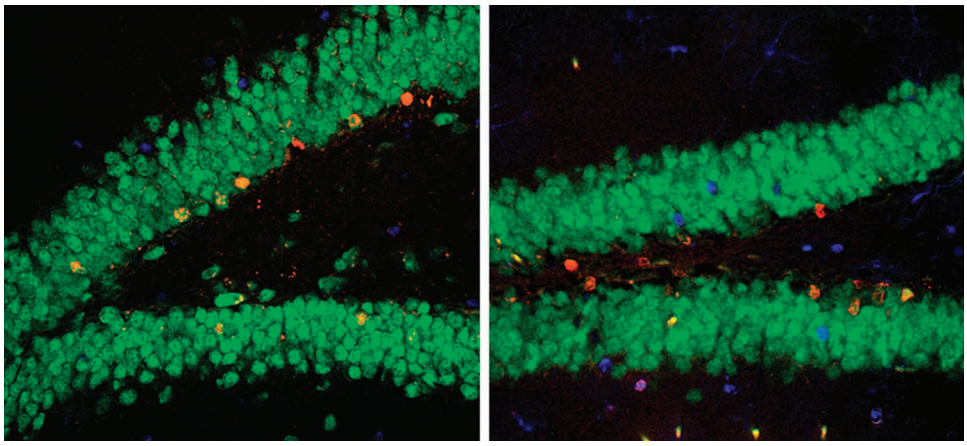
Aging also has been linked to a decline in the production of some neurotransmitters (Rieckmann & Nyberg, 2020). Reduction in acetylcholine is linked to memory loss, especially in people with Alzheimer disease (Barter & Foster, 2020; Shin & others, 2021). Severe reductions in dopamine are involved in a reduction in motor control in Parkinson disease (Boon & others, 2020).

Historically, as in the research just discussed, much of the focus on links between brain functioning and aging has been on volume of brain structures and regions. Recently, increased emphasis is being given to changes in myelination and neural networks (Dinsdale & others, 2021; Wen & others, 2020). Research indicates that demyelination (a deterioration in the myelin sheath that encases axons, which is associated with information processing) of the brain occurs with aging in older adults (Barter & Foster, 2020).

The Adapting Brain The human brain has remarkable repair capability (Esteves & others, 2021). Even in late adulthood, the brain loses only a portion of its ability to function, and the activities older adults engage in can influence the brain's development (Peven, Stillman, & Erickson, 2020; Toricelli & others, 2021). For example, an fMRI study found that higher levels of aerobic fitness were linked with greater volume in the hippocampus, which translates to better memory (Erickson & others, 2011).

Three areas reflect the adaptiveness of the brain in older adults: (1) the capacity to generate new neurons, (2) dendritic growth, and (3) delateralization. Researchers have found that **neurogenesis,** the generation of new neurons, does occur in lower mammalian species such as mice and rats (Schoenfeld & others, 2021). Also, research indicates that exercise and an enriched, complex environment can generate new brain cells in mice and that stress reduces the cells' survival rate (Kempermann, 2019) (see Figure 17). For example, in one study, mice in an enriched environment learned more flexibly because of adult hippocampal neurogenesis (Garthe, Roeder, & Kempermann, 2016). And another study revealed that coping with stress stimulated hippocampal neurogenesis in adult monkeys (Lyons & others, 2010). Researchers also have discovered that if rats are cognitively challenged to learn something, new brain cells survive longer (Shors, 2009).

neurogenesis The generation of new neurons.



Exercise Enriched Environment

FIGURE 17

GENERATING NEW NERVE CELLS IN ADULT MICE. Researchers have found that exercise (running) and an enriched environment (a larger cage and many toys) can cause brain cells to divide and form new brain cells (Kempermann, van Praag, & Gage, 2000). Cells were labeled with a chemical marker that becomes integrated into the DNA of dividing cells (red). Four weeks later, they were also labeled to mark neurons (nerve cells). As shown here, both the running mice and the mice in an enriched environment had many cells that were still dividing (red) and others that had differentiated into new nerve cells (orange).
Courtesy of Dr. Fred Gage, The Salk Institute for Biological Studies

It also is now accepted by most researchers that neurogenesis can occur in humans (Mandell & others, 2021). However, neurogenesis has been found in only two brain regions: the hippocampus (Snyder & Drew, 2020), which is involved in memory, and the olfactory bulb (Durante & others, 2021), which is involved in smell. Researchers currently are studying factors that might inhibit or promote neurogenesis, including various drugs, stress, and exercise (Kempermann, 2019; Liu & Nusslock, 2018). For example, in a recent study of mice, chronic stress followed by social isolation decreased hippocampal neurogenesis (Du Prees & others, 2021). They also are examining how the grafting of neural stem cells to various regions of the brain, such as the hippocampus, might increase neurogenesis (Tsutsui, 2020). And increasing attention is being given to the possible role neurogenesis might play in reversing the course of neurodegenerative diseases such as Alzheimer disease, Parkinson disease, and Huntington disease (Bovkova & others, 2020; Disouky & Lazarov, 2021).

Dendritic growth can occur in human adults, possibly even in older adults (Eliasieh, Liets, & Chalupa, 2007). One study compared the brains of adults at various ages (Coleman, 1986). From the forties through the seventies, the growth of dendrites increased. However, in people in their nineties, dendritic growth no longer occurred. This dendritic growth might compensate for the possible loss of neurons through the seventies but not in the nineties. Lack of dendritic growth in older adults could be due to a lack of environmental stimulation and activity.

Changes in lateralization may provide one type of adaptation in aging adults (Hong & others, 2015). Recall that lateralization is the specialization of function in one hemisphere of the brain or the other. Using neuroimaging techniques, researchers have found that brain activity in the prefrontal cortex is lateralized less in older adults than in younger adults when they are engaging in cognitive tasks (Cabeza, 2002; Esteves & others, 2021). For example, Figure 18 shows that when younger adults are given the task of recognizing words they have previously seen, they process the information primarily in the right hemisphere, while older adults doing the same task are more likely to use both hemispheres (Madden & others, 1999).

The decrease in lateralization in older adults might play a compensatory role in the aging brain (Hong & others, 2015). That is, using both hemispheres may improve the cognitive functioning of older adults (Duda & others, 2021).

What kinds of mental activities can slow the changes in the brain that occur with age? To read about how one group of researchers is seeking to answer this question, see the *Connecting with Research* interlude.

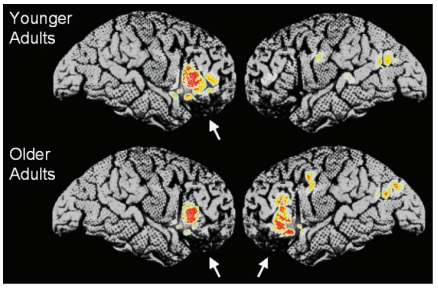


FIGURE 18

THE DECREASE IN BRAIN LATERALIZATION IN OLDER ADULTS. Younger adults primarily used the right prefrontal region of the brain (*top left photo*) during a recall memory task, whereas older adults used both the left and right prefrontal regions (*bottom two photos*).

The Nun Study

David Snowdon

Key Points:

- elderly nuns who are brain donors
- intellectually stimulating lives
- improved cognitive outcomes

The Nun Study, directed by David Snowdon, is an intriguing, ongoing investigation of aging in 678 nuns, many of whom have lived in a convent in Mankato, Minnesota (Pakhomov & Hemmy, 2014; Snowdon, 1997, 2002, 2003; Tyas & others, 2007; White & others, 2016). Each of the 678 nuns agreed to participate in annual assessments of her cognitive and physical functioning. The nuns also agreed to donate their brains for scientific research when they die, and they are the largest group of brain donors in the world. Examination of the nuns' donated brains, as well as those donated by others, has led neuroscientists to believe that the brain has a remarkable capacity to change and grow, even in old age. The Sisters of Notre Dame in Mankato lead an intellectually challenging life, and brain researchers believe this contributes to their quality of life as older adults and possibly to their longevity.

Findings from the Nun Study so far include the following:

- Positive emotions early in adulthood were linked to longevity (Danner, Snowdon, & Friesen, 2001). Handwritten autobiographies from 180 nuns, composed when they were 22 years of age, were scored for emotional content. The nuns whose early writings had higher scores for positive emotional content were more likely to still be alive at 75 to 95 years of age than their counterparts whose early writings were characterized by negative emotional content.
- Sisters who had taught for most of their lives showed more moderate declines in intellectual skills than those who had spent most of their lives in service-based tasks, a finding supporting the notion that stimulating the brain with intellectual activity keeps neurons healthy and alive (Snowdon, 2002).
- An analysis of essays written when the nuns were 18 to 32 years of age found that those whose essays reflected a higher level of self-reflection and independence in decision making lived longer (Weinstein & others, 2019).

This study and other research provide hope that scientists will discover ways to tap into the brain's capacity to adapt in order to prevent and treat brain diseases (Alexopoulos & Kelly, 2017). For example, scientists might learn more effective ways to improve older adults' cognitive functioning, reduce Alzheimer disease, and help older adults recover from strokes (Lovden, Backman, & Lindenberger, 2017). Even when areas of the brain are permanently damaged by stroke, new message routes can be created to get around the blockage or to resume the function of the damaged area, indicating that the brain does have the capacity to adapt.

(a)

(b)

(*a*) Sister Marcella Zachman (*left*) finally stopped teaching at age 97. Now, at 99, she helps ailing nuns exercise their brains by quizzing them on vocabulary or playing a card game called Skip-Bo, at which she deliberately loses. Sister Mary Esther Boor (*right*), also 99 years of age, is a former teacher who stays alert by doing puzzles and volunteering to work the front desk. (*b*) A technician holds the brain of a deceased Mankato nun. The nuns donate their brains for research that explores the effects of stimulation on brain growth. (*Both*): James Balog

Although the Nun Study's results are intriguing, an order of nuns is in some ways a self-selected group whose members may come to share many social and environmental characteristics through long years of living together. How might future researchers account for any potential biases in such studies?

Review *Connect* Reflect

LG2 Describe how the brain changes through the life span.

Review

- What are the major areas of the brain, and how does it process information?
- How does the brain change during infancy?
- What characterizes the development of the brain in childhood?
- How can the changes in the brain during adolescence be summarized?
- What is the aging brain like?

Connect

3 Sleep

LG3 Summarize how sleep patterns change as people develop.

Why Do We Sleep? | Infancy | Childhood | Adolescence and Emerging Adulthood | Adulthood and Aging

Sleep restores, replenishes, and rebuilds our brains and bodies. What purposes does sleep serve in people's lives? How do sleep patterns change across the life span?

WHY DO WE SLEEP?

A number of theories have been proposed about why we sleep. From an evolutionary perspective, all animals sleep, and this sleep likely is necessary for survival. Thus, sleep may have developed because animals needed to protect themselves at night. A second perspective is that sleep is restorative, with sleep replenishing and rebuilding the brain and body after the day's activities. In support of this restorative function, many of the body's cells show increased production and reduced breakdowns of proteins during sleep (Ferrarelli & others, 2019). Further, a current hypothesis is that sleep is essential to clearing out waste in neural tissues, such as metabolites and cerebrospinal fluid (Dai & others, 2018). A third perspective is that sleep is critical for brain plasticity (Brinkman, Reddy, & Sharma, 2020). For example, neuroscientists recently have argued that sleep increases synaptic connections between neurons (Tononi & Cirelli, 2020). These increased synaptic connections during sleep have been linked to improved consolidation of memories (Almeida-Filho, Queiroz, & Ribeiro, 2018). Also, a recent study revealed that sleep-specific brain activity restores performance by actively refining brain plasticity (Nissen & others, 2021). Further, research indicates that not only can sleep improve memory, but also losing just a few hours of sleep a night has negative effects on attention, reasoning, and decision making (Spruyt & others, 2019).

In sum, sleep likely serves a number of important functions, with no one theory accounting for all of these functions. Let's now turn our attention to how sleep functions at different points in the human life span.

Sleep that knits up the ravelled sleave of care . . . Balm of hurt minds, nature's second course. Chief nourisher in life's feast.

—William Shakespeare
English Playwright, Late 16th and Early 17th Century

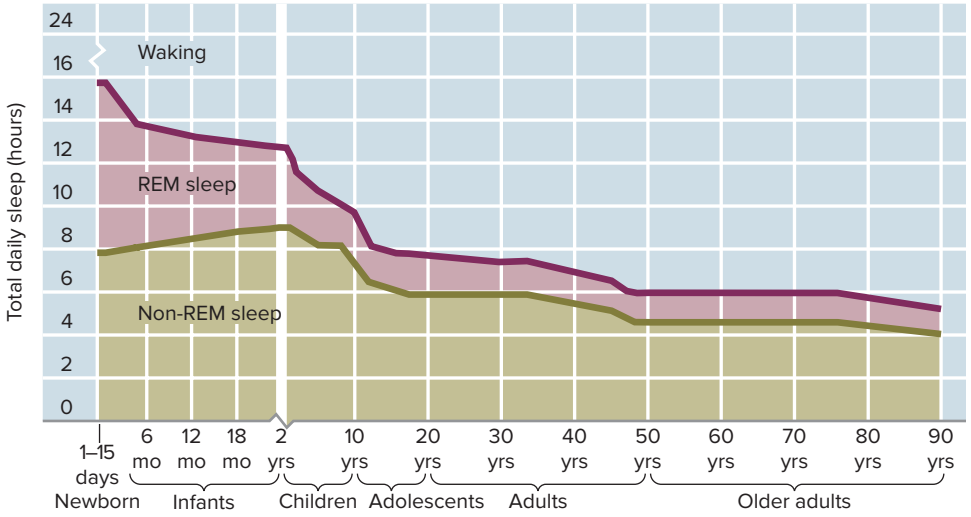
INFANCY

How much do infants sleep? Can any special problems develop regarding infants' sleep?

The Sleep/Wake Cycle When we were infants, sleep consumed more of our time than it does now. Newborns sleep 16 to 17 hours a day, although some sleep more and others

FIGURE **19**

SLEEP ACROSS THE HUMAN LIFE SPAN



less—the range is from a low of about 10 hours to a high of about 21 hours per day. Recently, the World Health Organization (WHO) recommended that infants 0 to 3 months of age should get 14 to 17 hours of good-quality sleep daily and 4- to 12-month-olds 12 to 16 hours of good-quality sleep daily (Willumsen & Bull, 2020). WHO also recommended that 1- to 2-year-olds should get 11 to 14 hours of good-quality sleep daily.

The most common infant sleep-related problem reported by parents is nighttime waking. Surveys indicate that 20 to 30 percent of infants have difficulty going to sleep and staying asleep at night (Sadeh, 2008). Inconsistent bedtime routines (Covington & others, 2021), maternal depression (Cook & others, 2020), and a higher amount of screen time are linked to infant sleep problems (Chen & others, 2019).

Is this a good sleep position for this 3-month-old infant? Why or why not?
Maria Teijeiro/Cultura/Getty Images

REM Sleep A much greater amount of time is taken up by REM (rapid eye movement) sleep in infancy than at any other point in the life span (Horne, 2020). Figure 19 shows developmental changes in the average number of total hours spent in REM and non-REM sleep. Unlike adults, who spend about one-fifth of their night in REM sleep, infants spend about half of their sleep time in REM sleep, and they often begin their sleep cycle with REM sleep rather than non-REM sleep. By the time infants reach 3 months of age, the percentage of time they spend in REM sleep decreases to about 40 percent, and REM sleep no longer begins their sleep cycle.

Why do infants spend so much time in REM sleep? Researchers are not certain. The large amount of REM sleep may provide infants with added self-stimulation, since they spend less time awake than do older children. REM sleep also might promote the brain's development in infancy (Del Rio-Bermudez & Blumberg, 2018).

When adults are awakened during REM sleep, they frequently report that they have been dreaming, but when they are awakened during non-REM sleep they are much less likely to report having been dreaming (Cartwright & others, 2006). Since infants spend more time than adults in REM sleep, can we conclude that they dream a lot? We don't know whether infants dream or not, because they don't have any way of reporting dreams.

SIDS **Sudden infant death syndrome (SIDS)** is a condition that occurs when infants stop breathing, usually during the night, and die suddenly without an apparent cause. SIDS remains the most frequent cause of infant death in the United States, with nearly 3,000 infant deaths attributed to it annually (Heron, 2016). Risk of SIDS is highest at 2 to 4 months of age (NICHD, 2021).

Since 1992, the American Academy of Pediatrics (AAP) has recommended that infants be placed to sleep on their backs to reduce the risk of SIDS, and the frequency of prone (stomach) sleeping among U.S. infants and infants in many other countries has dropped dramatically (Osberg, Kalstad, & Stray-Pedersen, 2021). Researchers have found that the rate of SIDS does indeed decrease when infants sleep on their backs rather than their stomachs or sides (Byard, 2021). Why? Because sleeping on their backs increases their access to fresh air and reduces their chances of getting overheated.

sudden infant death syndrome (SIDS) Condition in which an infant stops breathing, usually during the night, and suddenly dies without an apparent cause.

In addition to sleeping in a prone position (stomach down), researchers have found that the following are risk factors for SIDS: heart arrhythmias (Liebrechts-Akkermann & others, 2020), abnormal brain stem function involving the neurotransmitter serotonin (Cummings & Leiter, 2020), low birth weight (Horne & others, 2002), being an African American or Alaska Eskimo infant (Moon & others, 2017), not being breast fed (Cowgill, 2020), living in lower SES/poverty conditions (Drake & others, 2020), being exposed to cigarette smoke (U.S. Preventive Services Task Force & others, 2021), and sharing the same bed with parents (Osberg, Kalstad, & Stray-Pedersen, 2021).

What characterizes children's sleep?
S. Olsson/PhotoAlto

Sleep and Cognitive Development Infant sleep is being studied for its possible role in children's cognitive development (Camerota & others, 2020). A recent study found that infants with shorter sleep duration were characterized by a lower level of cognitive and language development at 2 years of age (Smithson & others, 2018). In addition, a recent study indicated that shorter sleep duration at 3, 8, and 24 months was linked to inattentive and hyperactivity symptoms at 5 years of age (Huhdanpaa & others, 2019). The links between infant sleep and children's cognitive functioning likely occur because of sleep's role in brain maturation and memory consolidation, which may improve daytime alertness and learning.

CHILDHOOD

Getting a good night's sleep is important for children's development. Recently, the World Health Organization (WHO) concluded that 3- to 4-year-old children should have 10 to 13 hours of good- quality sleep, which may include a nap, with consistent sleep and wake-up times (Willumsen & Bull, 2020). In a recent study of Chinese preschool children, only 29.5 percent of the children met the WHO sleep guideline of 10 to 13 hours of good quality sleep (Guan & others, 2020).

In some cases, young children's sleep problems are related to parental influences. For example, in a recent observational study, preschool children who had better-quality interactions with their parents (more harmonious and reciprocal) had longer sleep duration than their counterparts who had lower-quality interactions (more indifferent and conflictual) with their parents (Dubois-Comtois & others, 2020).

Children can experience a number of sleep problems. These include narcolepsy (extreme daytime sleepiness) (Ingram & others, 2021), insomnia (difficulty getting to sleep or staying asleep) (Lunsford-Avery & others, 2021), and nightmares (Harb & Schultz, 2020). Among the developmental problems associated with sleep issues in young children are being overweight or obese (Liberali & others, 2021) and having attention deficit hyperactivity disorder (ADHD) (Bioulac & others, 2020). For example, in a recent study, having nightmares at 24 months and restless sleep at 48 months were linked to ADHD at 11 years of age (Carpena & others, 2020).

ADOLESCENCE AND EMERGING ADULTHOOD

Might changing sleep patterns in adolescence contribute to adolescents' health-compromising behaviors? Recently there has been a surge of interest in adolescent sleep patterns (Simon & others, 2021; Trosman & Ivanenko, 2021). In a recent national survey of youth, only 25 percent of U.S. adolescents reported getting 8 or more hours of sleep on an average school night, compared with 32 percent who had reported getting this much sleep in a study conducted 4 years earlier (Kann & others, 2018). In the same survey, the percentage of adolescents getting this much sleep on an average school night decreased as they got older.

Getting too little sleep in adolescence is linked to a number of problems. In a study of 13- to 19-year-olds in Singapore, short sleep duration (less than 7 hours) on school nights was associated with an increased risk of being overweight, having depressive symptoms, being less motivated, not being able to concentrate adequately, having a high level of anxiety, and

What are some developmental changes in sleep patterns during adolescence? How might these changes influence alertness at school?
FatCamera/E+/Getty Images

engaging in self-harm/suicidal thoughts (Yeo & others, 2019). In a longitudinal study in which adolescents completed an activity diary every 14 days in ninth, tenth, and twelfth grades, regardless of how much time students spent studying each day, when the students sacrificed sleep time to study more than usual, they had difficulty understanding what was taught in class and were more likely to struggle with class assignments the next day (Gillen-O'Neel, Huynh, & Fuligni, 2013). Further, a recent study of adolescents indicated that insufficient sleep was associated with alcohol and marijuana use (Kwon & others, 2020).

Why are adolescents getting too little sleep? Among the explanations offered are increased use of electronic media, increased caffeine intake, and changes in the brain, coupled with early school start times (Kokka & others, 2021). Recent research indicated that frequency of cordless telephone calls, mobile phone dependency, and tablet use were linked to sleep problems in adolescence (Cabre-Riera & others, 2019). Caffeine intake by adolescents also is associated with insufficient sleep (Galland & others, 2020). The link between caffeine consumption and daytime sleepiness is related to lower academic achievement (James, Kristjansson, & Sigfusdottir, 2011).

Mary Carskadon (2002, 2006, 2011, 2020, Carskadon & Barker, 2020) has conducted a number of research studies on adolescent sleep patterns. She has found that adolescents sleep an average of 9 hours and 25 minutes when given the opportunity to sleep as long as they like. Most adolescents get considerably less sleep than this, especially on school nights. This creates a sleep debt that adolescents often try to make up on the weekend. Carskadon also has found that older adolescents are often more sleepy during the day than are younger adolescents. She concludes that this is not because of factors such as academic work and social pressures. Rather, her research suggests that adolescents' biological clocks undergo a hormonal phase shift as they get older. This shift pushes the time of wakefulness to an hour later than when they were young adolescents. Carskadon has found that the shift is caused by a delay in the nightly presence of the hormone melatonin, which is produced by the brain's pineal gland in preparing the body for sleep. Melatonin is secreted at about 9:30 p.m. in younger adolescents but is produced approximately an hour later in older adolescents, which delays the onset of sleep.

Carskadon determined that early school starting times can result in grogginess and lack of attention in class and poor performance on tests. Based on this research, some schools are now starting later (Gariepy & others, 2017). For example, school officials in Edina, Minnesota, made the decision to start classes at 8:30 a.m. instead of 7:25 a.m. Discipline problems dropped, and so did the number of students reporting illness or depression. Test scores in Edina improved for high school students but not for middle school students—results that support Carskadon's theory that older adolescents are affected more severely by early school start times than younger adolescents are. Further, in a recent study, when the Seattle School District delayed the school start time for secondary school students, it resulted in a 34-minute average increase in sleep duration, a 4.5 percent improvement in grades, and increased school attendance (Dunster & others, 2018). The American Academy of Pediatrics has recommended that schools institute start times between 8:30 and 9:30 a.m. to improve adolescents' academic performance and quality of life (Adolescent Sleep Working Group, AAP, 2014).

In Mary Carskadon's sleep laboratory at Brown University, an adolescent girl's brain activity is being monitored. Carskadon (2005) says that in the morning, sleep-deprived adolescents' "brains are telling them it's nighttime . . . and the rest of the world is saying it's time to go to school" (p. 19).
Courtesy of Jim LoScalzo

Do sleep issues continue into emerging adulthood? Research indicates that they do (Galambos, Howard, & Maggs, 2011). A research review concluded that approximately 70 percent of college students do not get adequate sleep and 50 percent report daytime sleepiness (Hershner & Chervin, 2015). Also, in one study, the weekday bedtimes and rise times of first-year college students were approximately 1 hour and 15 minutes later than those of seniors in high school (Lund & others, 2010). However, the first-year college students had later bedtimes and rise times than third- and fourth-year college students, indicating that at about 20 to 22 years of age, a reversal in the timing of bedtimes and rise times occurs.

In this study, poor-quality sleep was linked to worse physical and mental health, and the students reported that emotional and academic stress negatively affected their sleep.

Other recent research provides further insight into sleep problems during emerging adulthood. A recent study of college students indicated that shorter sleep duration was associated with increased suicide risk (Becker & others, 2018a). In another recent study of college students, 27 percent described their sleep as poor and 36 percent reported getting 7 hours or less of sleep per night (Becker & others, 2018b). Also, in a recent study of college students, sleep deprivation was linked to having a lower grade point average and delayed college graduation (Chen & Chen, 2021).

Research also indicates that daytime activities can contribute to sleep problems. In a recent study of female college students, poorer sleep quality was associated with smartphone dependence and less effective stress management (Wang & others, 2019). In addition, research indicates that higher consumption of energy drinks is linked to sleep problems in college students (Faris & others, 2017).

Many college students occasionally or often pull an all-nighter to cram for an exam. Recently, the National Sleep Foundation (2019) described why this might not be a good idea and could harm exam performance: It can distort your memory, cause thinking to be less clear, and impair concentration. Thus, exam performance will likely be much better if you engage in effective planning, effective time management, and spread your studying over a number of days and weeks.

ADULTHOOD AND AGING

Adolescents and emerging adults are not the only ones who are getting inadequate sleep. Many young, middle-aged, and older adults also are sleep-deprived. The National Sleep Foundation (2020) recommends that young adults get 7 to 9 hours of sleep a night, although many adults do not get this much sleep (Mamun & others, 2020). A statement by the American Academy of Sleep Medicine and Sleep Research Society (Luyster & others, 2012) emphasized that chronic sleep deprivation may contribute to cardiovascular disease, a shortened life span, and cognitive and motor impairment that increase the risk of motor vehicle crashes and work-related accidents.

In an analysis of sleep patterns from 20 to 90 years of age, total sleep for males decreased about 8 minutes per decade for males and about 10 minutes per decade for females as they got older (Dorffner, Vitr, & Anderer, 2015). Also in this study, as individuals aged, they engaged in more light sleep and less deep sleep. Beginning in the forties, wakeful periods are more frequent and there is less of the deepest type of sleep. The amount of time spent lying awake in bed at night begins to increase in middle age, which can produce a feeling of being less rested in the morning (Abbott, 2003). Sleep problems in middle-aged adults are more common among individuals who take a higher number of prescription drugs, are obese, have cardiovascular disease, or are depressed (Miner & Kryger, 2017).

Beginning in middle adulthood and continuing through late adulthood, the timing of sleep also changes. Many middle-aged and older adults go to bed earlier at night and wake up earlier in the morning (Liu & Liu, 2005). Many older adults also take a nap in the afternoon.

The National Sleep Foundation (2020) recommends that middle-aged adults get 7 to 9 hours of sleep and that older adults get 7 to 8 hours of sleep per night. In a recent Norwegian study of individuals 40 years of age and older, 42 percent of women and 52 percent of men reported sleeping less than 7 hours per night (Sivertsen & others, 2021). Inadequate sleep is problematic for middle aged and older adults, but so is sleeping too many hours daily. Why? Excessively long sleep duration is often an indicator of less effective physical and cognitive functioning (Nutakor & others, 2020).

Many of the sleep problems of middle-aged and older adults are associated with health problems (Liu & others, 2021). For example, one study found that middle-aged adults who sleep less than 6 hours per night on average had an increased risk of developing stroke symptoms (Ruiter & others, 2012). A recent study also revealed that older adults with major depression reported having poor sleep quality (Pye & others, 2021). In addition, sleep difficulties are increasingly recognized as a risk factor for Alzheimer disease (Andre & others, 2021). Further, sleep problems in middle and late adulthood are linked to cognitive decline (Djonlagic & others, 2021; Kohn & others, 2020). For example, one study revealed that poor sleep quality in middle adulthood was linked to a lower level of executive function, lower processing speed, higher rates of learning difficulty, and poorer memory recall (Kaur & others, 2019). And a recent study of

older adults found that a higher frequency and duration of awakenings throughout the night were linked to higher level of frailty and shorter longevity (Guida & others, 2021).

The following strategies can help older adults sleep better at night: avoid caffeine, avoid over-the-counter sleep remedies, stay physically active during the day, stay mentally active, and limit naps. Supporting the benefits of physical activity, one study of older adults indicated that walking at or above the internationally recommended level of 150 minutes per week predicted a lower likelihood of problems with sleep onset or sleep maintenance 4 years later (Hartescu, Morgan, & Stevinson, 2016). And in a recent study of individuals 60 years of age and older, for those who had been sleeping 7 hours or less per night, replacing 30 minutes of sedentary activity with 30 minutes of moderate to vigorous physical activity per day resulted in improved cognitive function (memory, executive function, and processing speed, for example) (Wei & others, 2021).

4 Longevity and Biological Aging

LG4 Explain longevity and the biological aspects of aging.

Life Expectancy and Life Span | Centenarians | Biological Theories of Aging

How long do most people live, and what distinguishes people who live a very long time? What is it like to live to a very ripe old age, and why do we age in the first place?

LIFE EXPECTANCY AND LIFE SPAN

To me old age is always fifteen years older than I am.

—Bernard Baruch
American Statesman, 20th Century

We are no longer a youthful society. As more individuals live to older ages, the proportion of individuals at different ages has become increasingly similar. Indeed, the concept of a period called "late adulthood" is a recent one—until the twentieth century, most individuals died before they reached 65. A much greater percentage of persons live to older ages today. However, the life span has remained virtually unchanged since the beginning of recorded history. **Life span** is the upper boundary of life, the maximum number of years an individual can live. The maximum life span of humans is approximately 120 to 125 years of age.

Life expectancy is the number of years that the average person born in a particular year will probably live. The average life expectancy of individuals born today in the United States is 78.6 years (Xu & others, 2020). Sixty-five-year-olds in the United States today can expect to live an average of 19.5 more years (20.7 for females, 18.1 for males) (Xu & others, 2020). Older adults who are 100 years of age can only expect to live an average of 2.3 years longer (U.S. Census Bureau, 2011). Keep in mind that it is not just improvements in the health and well-being of adults that have contributed to increased longevity but also the substantial reduction in infant deaths in recent decades.

life span The upper boundary of life, which is the maximum number of years an individual can live. The maximum life span of humans is about 120 years of age.

However, because of the staggering number of deaths due to the COVID-19 pandemic, life expectancy projections in 2020 decreased by approximately one year in the United States (Andrasfay & Goldman, 2021). With a disproportionate number of deaths due to COVID-19 occurring among African Americans and Latinxs, decreases in their life expectancy are projected to be up to three to four times the decrease for non-Latinx Whites.

How does the United States fare in life expectancy, compared with other countries around the world? We do considerably better than some and somewhat worse than others. In 2018, Monaco had the highest estimated life expectancy at birth (89.4 years), followed by Japan, Singapore, and Macau (a region of China near Hong Kong) (85 years) (Geoba, 2019). Of 224 countries, the United States ranked 53rd at 78.6 years. The lowest estimated life expectancy in 2018 occurred in the African countries of South Africa (50.6), Chad (51), and Namibia (51). Differences in life expectancies across countries are due to factors such as health conditions and medical care throughout the life span.

In a recent analysis, projections of life expectancy in 2030 were made for 35 developed countries (Kontis & others, 2017). It was predicted that life expectancy in the United States would increase to 83.3 years for women and 79.5 years for men by 2030. However, although the United States is expected to increase in life expectancy, it had one of the lowest growth rates in life expectancy among all the countries in the study. South Korea is projected to have the highest life expectancy in 2030, with South Korean women predicted to have an average life expectancy of 90.8, making South Korea the first nation to break the 90-year life expectancy barrier. What explains the lower growth in life expectancy for the United States and the very high growth for South Korea? The United States has the highest child and maternal mortality rates, homicide rate, and body-mass index of high-income countries in the world. In South Korea, delayed onset of chronic diseases is occurring and children's nutrition is improving. South Korea also has a low rate of obesity, and blood pressure is not as high as it is in most countries.

Life expectancy also differs for various ethnic groups within the United States and for men and women. For example, in 2017 the life expectancy of African Americans (75.3 years) in the United States was 6.5 years lower than the life expectancy for Latinxs (81.8 years) and 3.2 years lower than for non-Latinx Whites (78.5 years) (Murphy & others, 2018). The fact that Latinxs live 3.2 years longer than non-Latinx Whites despite having lower educational attainment and income levels is called the "Latinx Health Paradox" (Atiemo & others, 2019; Tabler & others, 2020). Why does this discrepancy occur? Among the proposed reasons are migration patterns, extended family connections, and rates of smoking. In terms of migration patterns, Latinx immigrants who stay in the United States tend to be healthier than average, while those who return to their countries of origin tend to be older and less healthy. In terms of extended family connections, Latinxs provide more support and interaction to their relatives, resulting in less loneliness for Latinxs than for non-Latinx Whites (Brill, 2019). And in terms of smoking, Latinxs are less likely to smoke than non-Latinx Whites. In a recent study supporting the Latinx Health Paradox, older adult Latinxs reported being healthier than their non-Latinx White counterparts (Olsen, Basu Roy, & Tseng, 2019).

In 2018, the overall life expectancy in the United States for women was 81.2 years of age, and for men it was 76.2 years of age (Xu & others, 2020). Beginning in the mid-thirties, females outnumber males; this gap widens during the remainder of the adult years. By the time adults are 75 years of age, more than 61 percent of the population is female; among those who are 85 and over, almost 70 percent are female. Why can women expect to live longer than men? Social factors such as health attitudes, habits, lifestyles, and occupations are probably important (Saint Onge, 2009). For example, men are more likely than women to die from the leading causes of death in the United States, such as cancer of the respiratory system, motor vehicle accidents, cirrhosis of the liver, emphysema, and coronary heart disease (especially stroke) (Alfredsson & others, 2018). These causes of death are associated with lifestyle. For example, the sex difference in deaths due to lung cancer and emphysema occur because men tend to be heavier smokers than women. However, women are more likely than men to die from Alzheimer disease and some aspects of cardiovascular disease, such as hypertension-related problems (Ostan & others, 2016).

To be seventy years young is sometimes far more cheerful and hopeful than to be forty years old.

–Oliver Wendell Holmes, Sr.
American Physician, 19th Century

What is the Latinx health paradox?
Ron Levine/Getty Images

The sex difference in longevity also is influenced by biological factors (Sampathkumar & others, 2020). In virtually all species of animals, females outlive males. Among humans, women have more resistance to infections and degenerative diseases (Pan & Chang, 2012). For example, the woman's estrogen production helps to protect her from hardening of the arteries. And the additional X chromosome that women carry in comparison with men may be associated with the production of more antibodies to fight off disease. In 1979, the gender difference in longevity favored women by 7.8 years, but in 2018 the difference had decreased to 5.0 years (Xu & others, 2020).

CENTENARIANS

In industrialized countries, the number of centenarians (individuals 100 years and older) is increasing at a rate of approximately 7 percent each year (Perls, 2007). In the United States, there were only 15,000 centenarians in 1980, but the total had risen to 50,000 by 2000 and to 82,000 by 2016 (Buchholz, 2020). The number of U.S. centenarians is projected to reach 589,000 by 2060. The United States has the most centenarians, followed by Japan, China, and England/Wales (Goodman, 2019). In a recent (2020) list of the world's oldest living people, there were no males in the top 50 oldest individuals. As of June 2020, the oldest living person in the world was 117-year-old Kane Tanaka of Japan. The oldest living person in the United States was 114-year-old Hester Ford who lives in Charlotte, North Carolina.

Many people expect that "the older you get, the sicker you get." However, researchers are finding that this is not true for some centenarians (Anderson & others, 2019). The researchers have found that chronic high-mortality diseases are markedly delayed for many years in centenarians, with many not experiencing disability until near the end of their lives (Ismail & others, 2016). And a study of centenarians from 100 to 119 years of age found that the older the age group (110 to 119 compared with 100 to 104, for example), the later the onset of diseases such as cancer and cardiovascular disease, as well as functional decline (Andersen & others, 2012). The research just described was conducted as part of the ongoing New England Centenarian Study.

In addition to the New England Centenarian Study, another major ongoing study is the Georgia Centenarian Study conducted by Leonard Poon and his colleagues (Cho & others, 2020; de Rosa & others, 2020; Johnson-Nicholson & others, 2021; Lee, Martin, & Poon, 2017; Poon & others, 2010, 2012). In a research review, Poon and his colleagues (2010) concluded that social dynamics involving life events (experiencing a higher number of negative life events is linked to lower self-rated health), personality (conscientiousness is

Three participants in the New England Centenarian Study: (*Left*) At 107 years of age, Agnes Fenton of Englewood, New Jersey, said she didn't feel any older than when she was 15. She still cooked her own meals and her only health complaint was arthritis in her hand. (*Center*) Louis Carpenter, age 99, lived in the Boston area and every day carved wooden figures in his basement shop. Louis said his memory was still terrific. (*Right*) Edythe Kirchmaier of the New York City area was Facebook's oldest user at 105 years of age. As of July 2014, Edythe had more than 51,000 Facebook followers! She volunteered every week at her favorite charity, still drove her car, and frequently used the Internet to look up information.

positively associated with higher levels of physical and mental health), cognition (cognitive measures are better predictors of mental health than physical health), and socioeconomic resources and support systems (social, economic, and personal resources are related to mental and physical health) contribute to the health and quality of life of older adults, including centenarians. Yet another major study is the Chinese Longitudinal Healthy Longevity Survey, which includes older adults, some of whom are centenarians (Feng & others, 2021; Xiao, Wu, & Zeng, 2019; Wang & others, 2021; Zhang & others, 2021). In one investigation involving this sample, Chinese centenarians showed better coping and adjustment mechanisms (greater personal tenacity, optimism, coping with negative moods, secure relationships, and personal control) than their Chinese counterparts in their nineties, eighties, or seventies (Zeng & Shen, 2010).

How do centenarians view their lives? What are their explanations for being able to live so long?

- Elza Winn concludes that he has been able to live so long because he made up his mind to do so. He says he was thinking about dying when he was 77 but decided to wait awhile (Segerberg, 1982).
- Misao Okawo, at 117 years of age, was the oldest person in the world in 2016, then died later that year. A resident of Osaka, Japan, she attributed her longevity to eating sushi, getting eight hours of sleep per night, and being able to relax.
- Gertrude Weaver, who at 116 years of age was the oldest person in the United States in 2016, lived in Arkansas and said her faith was what kept her alive. She was a wheelchair-dancing enthusiast for many years.
- Simo Radulovich thought that living to an old age required having a sense of humor, living moderately, and sleeping well. He engaged in exercise games with his friends every day and said he had never been afraid of anything and had always had the confidence to get through the tough times (O'Dell, 2013).
- Mary Butler said that finding something to laugh about every day helped her live longer. She thought a good laugh was better than a dose of medicine anytime (Segerberg, 1982).
- Duran Baez remarried at 50 and went on to have 15 more children. At 100 years of age, he was asked if he had any ambitions he had not yet realized. Duran replied, "No" (Segerberg, 1982).
- Frenchwoman Jeanne Louise Calment was the world's longest-living person. She died at 122 years of age in 1997 and attributed her longevity to a number of things, including not worrying "about things you can't do anything about," having an occasional glass of Port wine and a diet rich in olive oil, and keeping a sense of humor. Regarding her ability to live so long, she once said that God must have forgotten about her. On her 120th birthday, an interviewer asked her what kind of future she anticipated. She replied, "A very short one." Becoming accustomed to the media attention she got, at 117 she stated, "I wait for death . . . and journalists." She walked, biked, and exercised a lot. Jeanne Louise began taking fencing lessons at 85 and rode a bicycle until she was 100.

What chance do you have of living to be 100? Genes play an important role in surviving to an extreme old age (Yuan & others, 2020). There is increasing interest in studying susceptibility genes (Yuan & others, 2021), which make an individual more vulnerable to specific diseases or acceleration of aging, and longevity genes (Torres & others, 2021), which make an individual less vulnerable to certain diseases and more likely to live to an older age. But as indicated in Figure 20, there are also other factors at work, such as family history, health (weight, diet, smoking, and exercise), education, personality, and lifestyle (Kokkinos & others, 2021). The epigenetic approach focuses increasing interest on determining gene × environment (G × E) interactions that influence development (Amenyah & others, 2020). A Chinese study found that a combination of particular FOXO genotypes and drinking tea was associated with the prevention of cognitive decline in the oldest-old, aged 92+ (Zeng & others, 2016). Nonetheless, most people are not biologically capable of living to be 100 (Chapman & others, 2019).

Frenchwoman Jeanne Louise Calment, shown here celebrating her 117th birthday. Calment was the oldest documented living person. She lived to be 122 years of age.

Life Expectancy

This test gives you a rough guide for predicting your longevity. The basic life expectancy for men is age 75, and for women it is 81. Write down your basic life expectancy. If you are in your fifties or sixties, you should add ten years to the basic figure because you have already proved yourself to be a durable individual. If you are over age 60 and active, you can even add another two years.

Decide how each item applies to you and add or subtract the appropriate number of years from your basic life expectancy.

1. Family history
___ Add five years if two or more of your grandparents lived to 80 or beyond.
___ Subtract four years if any parent, grandparent, sister, or brother died of a heart attack or stroke before 50.
___ Subtract two years if anyone died from these diseases before 60.
___ Subtract three years for each case of diabetes, thyroid disorder, breast cancer, cancer of the digestive system, asthma, or chronic bronchitis among parents or grandparents.

2. Marital status
___ If you are married, add four years.
___ If you are over 25 and not married, subtract one year for every unmarried decade.

3. Economic status
___ Add two years if your family income is over $60,000 per year.
___ Subtract three years if you have been poor for the greater part of your life.

4. Physique
___ Subtract one year for every 10 pounds you are overweight.
___ For each inch your girth measurement exceeds your chest measurement deduct two years.
___ Add three years if you are over 40 and not overweight.

5. Exercise
___ Add three years if you exercise regularly and moderately (jogging three times a week).
___ Add five years if you exercise regularly and vigorously (long-distance running three times a week).
___ Subtract three years if your job is sedentary.
___ Add three years if your job is active.

6. Alcohol
___ Add two years if you are a light drinker (one to three drinks a day).
___ Subtract five to ten years if you are a heavy drinker (more than four drinks per day).
___ Subtract one year if you are a teetotaler.

7. Smoking
___ Subtract eight years if you smoke two or more packs of cigarettes per day.
___ Subtract two years if you smoke one to two packs per day.
___ Subtract two years if you smoke less than one pack.
___ Subtract two years if you regularly smoke a pipe or cigars.

8. Disposition
___ Add two years if you are a reasoned, practical person.
___ Subtract two years if you are aggressive, intense, and competitive.
___ Add one to five years if you are basically happy and content with life.
___ Subtract one to five years if you are often unhappy, worried, and often feel guilty.

9. Education
___ Subtract two years if you have less than a high school education.
___ Add one year if you attended four years of school beyond high school.
___ Add three years if you attended five or more years beyond high school.

10. Environment
___ Add four years if you have lived most of your life in a rural environment.
___ Subtract two years if you have lived most of your life in an urban environment.

11. Sleep
___ Subtract five years if you sleep more than nine hours a day.

12. Temperature
___ Add two years if your home's thermostat is set at no more than 68° F.

13. Health care
___ Add three years if you have regular medical checkups and regular dental care.
___ Subtract two years if you are frequently ill.

___ **Your Life Expectancy Total**

FIGURE **20**
CAN YOU LIVE TO BE 100?

BIOLOGICAL THEORIES OF AGING

Even if we stay remarkably healthy, we begin to age at some point. In fact, life-span experts argue that biological aging begins at birth (Schaie, 2000). What are the biological explanations of aging? Intriguing biological explanations of why we age are provided by evolutionary theory, genetic/cellular process theories, and hormonal stress theory.

developmental **connection**
Culture
In Baltes' view, the benefits of evolutionary selection decrease with age and the need for culture increases with age. Connect to "Biological Beginnings."

Evolutionary Theory In the evolutionary theory of aging, natural selection has not eliminated many harmful conditions and nonadaptive characteristics in older adults. Why? Because natural selection is linked to reproductive fitness, which is present only in the earlier part of adulthood (Laisk & others, 2019). For example, consider Alzheimer disease, an irreversible brain disorder that does not appear until late middle adulthood or beyond. In evolutionary theory, if Alzheimer disease had occurred earlier in development, it might have been eliminated many centuries ago. One criticism is that the "big picture" idea of natural selection leading to the development of human traits and behaviors is difficult to refute or test because evolution occurs on a time scale that does not lend itself to empirical study. Another criticism is the failure of evolutionary theory to account for cultural influences (Singer, 2016).

Genetic/Cellular Process Theories Recent explanations of aging include cellular maintenance requirements and evolutionary constraints. In recent decades, there has been a significant increase in research on genetic and cellular processes involved in aging (Barter & Foster, 2020; Engin & Engin, 2021). Five such advances involve telomeres, free radicals, mitochondria, sirtuins, and the mTOR pathway.

Cellular Clock Theory **Cellular clock theory** is Leonard Hayflick's (1977) theory that cells can divide a maximum of about 75 to 80 times and that over time our cells become less capable of dividing. Hayflick found that cells extracted from adults in their fifties to seventies divided fewer than 75 to 80 times. Based on the ways cells divide, Hayflick places the upper limit of the human life span at about 120 to 125 years of age.

In the last decade, scientists have tried to bridge a gap in cellular clock theory (Di Micco & others, 2021; Toubiana & Selig, 2020). Hayflick did not know why cells die. The answer may lie at the tips of chromosomes, at telomeres, which are DNA sequences that cap chromosomes (Zhang & others, 2021).

Each time a cell divides, the telomeres become shorter and shorter (Chakravarti, LaBella, & DePinho, 2021) (see Figure 21). After about 70 or 80 replications, the telomeres are dramatically reduced and the cell no longer can reproduce. One study revealed that healthy centenarians had longer telomeres than unhealthy centenarians (Terry & others, 2008). Further, a recent study confirmed that shorter telomere length was linked to Alzheimer disease (Scarabino & others, 2017). And a recent research review concluded that lifestyle modifications involving exercise and diet show encouraging results for delaying telomere shortening (Qiao, Jiang, & Li, 2020).

Injecting the enzyme telomerase into human cells grown in the laboratory can substantially extend the life of the cells beyond the approximately 70 to 80 normal cell divisions. However, telomerase is present in approximately 85 percent of cancerous cells and thus may not produce healthy life extension of cells (Cleal, Norris, & Baird, 2018). To capitalize on the high presence of telomerase in cancerous cells, researchers currently are investigating gene therapies that inhibit telomerase and lead to the death of cancerous cells while keeping healthy cells alive (Prieto-Oliveira, 2021; Wu & others, 2020). A recent focus of these gene therapies is on stem cells and their renewal (Bonafe, Sabbatinelli, & Olivieri, 2020; Di Stefano & others, 2021). Telomeres and telomerase are increasingly thought to be key components of the stem cell regeneration process, providing a possible avenue to restrain cancer and delay aging (Brenner & Nandakumar, 2020).

Free-Radical Theory A second genetic/cellular process theory of aging is **free-radical theory,** which states that people age because when cells metabolize energy, the by-products include unstable oxygen molecules known as free radicals (Tabibzadeh, 2021). The free radicals ricochet around the cells, damaging DNA and other cellular structures (Kowalska & others, 2020). The damage can lead to a range of disorders, including cancer (Purohit, Simeone, & Lyssiotis, 2019) and arthritis (Mateen & others, 2019). Overeating is linked with an increase in free radicals, and researchers recently have found that calorie restriction—a diet restricted in calories although adequate in proteins, vitamins, and minerals—reduces the oxidative damage created by free radicals (Djordjevic, Loncarevic-Vasiljkovic, & Gonos, 2021). In a recent study of 57- to 83-year-olds, maintaining a healthy body weight was linked to reduced oxidative stress (Anusruti & others, 2020). In addition to considering dietary factors, researchers also are exploring the role that exercise might play in reducing oxidative damage in cells (Kruk, Kotarska, & Aboul-Enein, 2020).

Mitochondrial Theory There is increasing interest in the role that mitochondria—tiny bodies within cells that supply energy for function, growth, and repair—might play in aging (Toricelli & others, 2021) (See Figure 22). **Mitochondrial theory** states that aging is due to the decay of mitochondria. It appears that this decay is primarily due to oxidative damage and loss of critical micronutrients supplied by the cell (Lazo & others, 2021).

How do oxidative damage and loss of nutrients occur? Among the by-products of mitochondrial energy production are the free radicals just described. According to the mitochondrial theory, the damage caused by free radicals initiates a self-perpetuating cycle in which oxidative damage causes impairment of mitochondrial function, which results in the generation of even greater amounts of free radicals (Panel, Ghaleh, & Morin, 2018). The mitochondrial damage may lead to a range of disorders, including cardiovascular

sirtuins A family of proteins that have been proposed as having important influences on longevity, mitochondrial functioning in energy, calorie restriction benefits, stress resistance, and cardiovascular functioning.

mTOR pathway A cellular pathway that involves the regulation of growth and metabolism and has been proposed as a key aspect of longevity.

hormonal stress theory The theory that aging in the body's hormonal system can lower resistance to stress and increase the likelihood of disease.

disease (Manolis & others, 2021), neurodegenerative diseases such as Alzheimer disease (Calvo-Rodriguez & Bacskai, 2021), Parkinson disease (Yan & others, 2020), diabetic kidney disease (Xu, Kitada, & Koya, 2020), and impaired liver functioning (Prasun, Ginevic, & Oishi, 2021). Mitochondria also likely play important roles in neuronal plasticity (Lees, Johnson, & Ashby, 2020).

Sirtuin Theory **Sirtuins** are a family of proteins that have been linked to longevity, regulation of mitochondria functioning in energy, possible benefits of calorie restriction, stress resistance, diabetes, Alzheimer disease, Parkinson disease, and a lower incidence of cardiovascular disease and cancer (Liu & others, 2020; Shieh, Huang, & Lin, 2020). Two of the sirtuins, SIRT 1 and SIRT 6, are linked to DNA repair and greater longevity (Das, 2021).

mTOR Pathway Theory The **mTOR pathway** is a cellular pathway that involves the regulation of growth and metabolism. TOR stands for "target of rapamycin," and in mammals it is called mTOR. Rapamycin is a naturally derived antibiotic and immune system suppressant/modulator, first discovered in the 1960s on Easter Island. It has been commonly used and is FDA approved for preventing rejection of transplanted organs and bone marrow. Recently, proposals have been made that the mTOR pathway plays a central role in the life of cells, acting as a cellular router for growth, protein production/metabolism, and stem cell functioning (Daneshgar, Rabinovitch, & Dai, 2021; Wang & others, 2020). Some scientists also argue that the pathway is linked to longevity, the successful outcomes of calorie restriction, and reducing cognitive decline, and that it plays a role in a number of diseases, including cancer, cardiovascular disease, and Alzheimer disease (Dimri & Satyanarayana, 2020; Popova & Jucker, 2021). Rapamycin has not been approved as an anti-aging drug and has some serious side effects, including increased risk of infection and lymphoma, a deadly cancer.

Hormonal Stress Theory

The theories of aging that we have discussed so far attempt to explain aging at the evolutionary and genetic/cellular process levels. In contrast, **hormonal stress theory** argues that aging in the body's hormonal system can lower resistance to stress and increase the likelihood of disease.

Normally, when people experience stressors, the body responds by releasing certain hormones. As people age, the hormones stimulated by stress remain at elevated levels longer than when they were younger (Finch, 2011; Gekle, 2017). These prolonged, elevated levels of stress-related hormones are associated with increased risks for many diseases, including cardiovascular disease, cancer, diabetes, and hypertension (Li & others, 2020). Researchers are exploring stress buffering strategies, including exercise, in an effort to find ways to attenuate some of the negative effects of stress on the aging process (Leow & others, 2021).

A variation of hormonal stress theory has emphasized the contribution of a decline in immune system functioning with aging (Jones & others, 2021). In a recent study, the percentage of T cells (a type of white blood cell essential for immunity) decreased in older adults in their seventies, eighties, and nineties (Song & others, 2018). Aging contributes to immune system deficits that give rise to infectious diseases in older adults (Hopkin, Lord, & Chimen, 2021). The extended duration of stress and diminished restorative processes in older adults may accelerate the effects of aging on immunity.

Recently, new viral diseases have emerged that pose severe threats to the health of older adults. The death toll from the COVID-19 pandemic in 2020 illustrated the devastating impact of severe viral diseases on the already declining immune system function of older adults (Bajaj & others, 2021; Salimi & Hamlyn, 2020).

Conclusions

Which of these biological theories best explains aging? That question has yet to be answered. It likely will turn out that more than one—or perhaps all—of these biological processes contribute to aging. In a research analysis, it was concluded that aging is a very complex process involving multiple degenerative factors, including interacting evolutionary, genetic/cellular, and organ/hormonal level communications (de Magalhaes & Tacutu, 2016). Although there are some individual aging triggers such as telomere shortening, a full understanding of biological aging involves multiple processes operating at different biological levels (Toricelli & others, 2021).

Review *Connect* Reflect

LG4 Explain longevity and the biological aspects of aging.

Review

- What is the difference between life span and life expectancy? What sex differences exist in longevity?
- What do centenarians have in common?
- What are the main biological theories of aging?

Connect

- There are differences among biological, psychological, and social age. How do biological theories of aging inform these three different conceptions of age?

Reflect *Your Own Personal Journey of Life*

- To what age do you think you will live? Why? To what age would you like to live?

reach your **learning goals**

Physical Development and Biological Aging

1 Body Growth and Change

LG1 Discuss major changes in the body through the life span.

Patterns of Growth

- Human growth follows cephalocaudal (fastest growth occurs at the top) and proximodistal patterns (growth starts at the center of the body and moves toward the extremities).

Height and Weight in Infancy and Childhood

- Height and weight increase rapidly in infancy and then take a slower course during childhood.

Puberty

- Puberty is a brain-neuroendocrine process occurring primarily in early adolescence that provides stimulation for the rapid physical changes that accompany this period of development.
- A number of changes occur in sexual maturation. The growth spurt involves rapid increases in height and weight and occurs about two years earlier for girls than for boys.
- Extensive hormonal changes characterize puberty. Puberty began occurring much earlier in the twentieth century mainly because of improved health and nutrition. The basic genetic program for puberty is wired into the nature of the species, but nutrition, health, and other environmental factors affect the timing of puberty.
- Adolescents show heightened interest in their bodies and body images. Younger adolescents are more preoccupied with these images than older adolescents. Adolescent girls often have a more negative body image than do adolescent boys.
- Early maturation often favors boys, at least during early adolescence, but as adults, late-maturing boys have a more positive identity than do early-maturing boys. Early-maturing girls are at risk for a number of developmental problems.

Early Adulthood

- In early adulthood, height remains rather constant. Many individuals reach their peak of muscle tone and strength in their late teens and twenties; however, their physical capacity may decline during their thirties.

Middle Adulthood

- In middle adulthood, changes usually are gradual. Visible signs of aging, such as the wrinkling of skin, appear in the forties and fifties. Middle-aged individuals also tend to lose height and gain weight. Strength, joints, and bones show declines in middle age. The cardiovascular system declines in functioning, and lung capacity begins to decline, more so in smokers than nonsmokers.

- The climacteric is the midlife transition in which fertility declines. Menopause is the time in middle age, usually in the late forties or early fifties, when a woman has not had a menstrual period for a year. Men do not experience an inability to father children in middle age, although their testosterone level declines.

Late Adulthood

- In late adulthood, outwardly noticeable physical changes become more prominent, individuals get shorter, and weight often decreases because of muscle loss. The circulatory system declines further.

2 The Brain

LG2 Describe how the brain changes through the life span.

The Neuroconstructivist View

- This increasingly popular view of brain development states that biological processes and environmental conditions influence the brain's development; the brain has plasticity; and cognitive development is closely linked with brain development.

Brain Psychology

- The brain has two hemispheres, each of which has four lobes (frontal, occipital, temporal, and parietal).
- Throughout the brain, nerve cells called neurons process information. Communication among neurons involves the axon, dendrites, synapses, neurotransmitters, and the myelin sheath. Clusters of neurons, known as neural circuits, work together to handle specific types of information.

Infancy

- Researchers have found that early experience influences the brain's development. Myelination begins prenatally and continues after birth. In infancy, one of the most impressive changes in the brain is the enormous increase in dendrites and synapses. These connections between neurons are overproduced and then pruned. Specialization of functioning does occur in the brain's hemispheres, as in language, but for the most part both hemispheres are at work in most complex functions.

Childhood

- During early childhood, the brain and head grow more rapidly than any other part of the body. Researchers have found that dramatic anatomical changes in brain patterns occur from 3 to 15 years of age, often involving spurts of brain activity and growth.

Adolescence

- The corpus callosum, a large bundle of axon fibers that connects the brain's left and right hemispheres, thickens in adolescence, and this thickening improves the adolescent's ability to process information.
- The prefrontal cortex, the highest level of the frontal lobes that are involved in reasoning, decision making, and self-control, continues to mature through emerging adulthood or later.
- The amygdala, the part of the limbic system that is the seat of emotions such as anger, matures earlier than the prefrontal cortex. The later development of the prefrontal cortex combined with the earlier maturity of the amygdala may explain the difficulty adolescents have in putting the brakes on their emotional intensity.

Adulthood and Aging

- On average, the brain loses 5 to 10 percent of its weight between the ages of 20 and 90. Brain volume also decreases with aging. Shrinking occurs in some areas of the brain, such as the prefrontal cortex, more than in other areas.
- A general slowing of function of the central nervous system begins in middle adulthood and increases in late adulthood. A decline in the production of some neurotransmitters is related to aging.
- Neurogenesis has been demonstrated in lower mammals, but whether it occurs in human adults is still controversial. It appears that dendritic growth can occur in adults. The brain has the capacity to virtually rewire itself to compensate for loss in late adulthood. Brain lateralization usually decreases in older adults.

3 Sleep

LG3 Summarize how sleep patterns change as people develop.

Why Do We Sleep?

- A number of theories have been proposed about the functions of sleep, including evolutionary theory and sleep's role in survival; the role of sleep as a restorative function involving protein production and neural waste removal; and the role of sleep in brain plasticity. Sleep likely serves a number of important functions.

Infancy

- Newborns sleep about 16 to 17 hours a day. By about 4 months of age, most infants have sleep patterns similar to those of adults. REM sleep occurs more in infancy than in childhood and adulthood. A special concern is sudden infant death syndrome.

Childhood

- Most experts recommend that young children get 11 to 13 hours of sleep each night. Most young children sleep through the night and have one daytime nap. Inadequate sleep is linked to children's depression and attention problems. Children can experience a number of sleep problems.

Adolescence and Emerging Adulthood

- Many adolescents stay up later and sleep longer in the morning than they did when they were children. Recent interest focuses on biological explanations of these developmental changes in sleep during adolescence and their link to school success. Recent research indicates that a majority of first-year college students have sleep difficulties and that they go to bed even later and get up later than adolescents do. However, by the end of college they have begun to reverse this trend.

Adulthood and Aging

- An increasing concern is that adults do not get enough sleep. In middle age, wakeful periods may interrupt nightly sleep more often. Many older adults go to bed earlier and wake up earlier. Almost half of older adults report having some insomnia.

4 Longevity and Biological Aging

LG4 Explain longevity and the biological aspects of aging.

Life Expectancy and Life Span

- Life expectancy is the number of years an individual is expected to live when he or she is born. Life span is the maximum number of years any member of a species has been known to live. On average, females live about five years longer than males do. The sex difference is likely due to biological and social factors. An increasing number of individuals live to be 100 or older.

Centenarians

- Heredity, family history, health, education, personality, and lifestyle are important factors in living to be a centenarian. The ability to cope with stress also is important.

Biological Theories of Aging

- The evolutionary theory of aging proposes that natural selection has not eliminated many harmful conditions and nonadaptive characteristics in older adults; thus, the benefits conferred by evolution decline with age because natural selection is linked to reproductive fitness.
- One recent view is that aging is caused by a combination of cellular maintenance requirements and evolutionary constraints. Among the key genetic and cellular processes that have been proposed to explain aging are those involving telomeres, free radicals, mitochondria, sirtuins, and the mTOR pathway.
- According to hormonal stress theory, aging in the body's hormonal system can lower resilience and increase the likelihood of disease.

preview

Life is more than just existing. It is important to lead a healthy life. As we grow and develop through the life span, we have many opportunities to engage in health-enhancing or health-compromising behaviors, either by our choosing or because of the contexts provided by our caregivers. In this chapter, we will explore many aspects of health, including illness and disease, nutrition and eating behavior, exercise, and substance use.

1 Health, Illness, and Disease

LG1 Describe developmental changes in health.

- Children's Health
- Adolescents' Health
- Emerging and Young Adults' Health
- Health and Aging

Changing patterns of illness have fueled an interest in identifying not only biological causes of health, illness, and disease, but also psychological and sociocultural causes. With these multiple causes in mind, let's now examine changes in health throughout the life span.

CHILDREN'S HEALTH

Many factors affect children's health. In this chapter, we focus on two of the most important influences: prevention and poverty. We will also consider the health impact of immunization, accidents, and access to health care.

Prevention Although the risks children face from many diseases have greatly diminished, it is still important for parents to keep their children on a timely immunization schedule (Pollard & Bijker, 2021). The recommended ages for various immunizations are shown in Figure 1.

There is concern that in 2020–2021 the COVID-19 pandemic might have caused some parents to avoid taking their children to a physician for immunizations out of fear that they or their children might contract the virus at the doctor's office (Vogt & others, 2020). It is important for parents to take their children to a pediatrician for well-child visits and immunizations.

In addition to immunization, another important way to prevent health problems in children is to avoid accidents, which are the leading cause of death during childhood (Levi & others, 2020). In 2017, 32.9 percent of deaths among 1- to 9-year-old children were caused by unintentional injuries (Heron, 2019). Infants need close monitoring as they gain locomotor and manipulative skills at the same time that they are highly motivated to explore their environment (Loux & others, 2021). Aspiration of foreign objects, suffocation, falls, poisoning, burns, and motor vehicle accidents are among the most common accidents in infancy (Roldos, Farhat, & Moehlman, 2021). Drowning is the most common cause of accidental death in young children, followed by motor vehicle accidents. Children in poverty have higher rates of accidents, death, and asthma than do children from higher-income families (Chisholm & others, 2020).

The status of children's motor, cognitive, and socioemotional development makes their health-care needs unique (Telljohann & others, 2020). For example, think about how the motor skills of infants and young children are inadequate to ensure their personal safety while riding in an automobile. Adults must take preventive measures to restrain infants and young children in car seats (Scott & Gershoff, 2021; Sylvester & others, 2021). Young children also lack the cognitive skills, including reading ability, to discriminate between safe and unsafe household substances. And they may lack the impulse control to stop themselves from running out into a busy street while chasing a ball or toy.

Caregivers play an important role in promoting children's health (Garvis & Pendergast, 2020). An increasing number of studies reach the conclusion that children are at increased risk for health problems when they live in homes where a parent smokes (Ramos-Lopez & others, 2021). For example, a recent national study found that children with a smoker in the home were 30 percent more likely to be diagnosed with asthma than children with no smokers

Age	Immunization
Birth	Hepatitis B
2 months	Diphtheria Polio Influenza
4 months	Diphtheria Polio Influenza
6 months	Diphtheria Influenza
1 year	TB test
15 months	Measles Mumps Rubella Influenza
18 months	Diphtheria Polio
4 to 6 years	Diphtheria Polio
11 to 12 years	Measles Mumps Rubella
14 to 16 years	Tetanus-diphtheria

FIGURE 1
RECOMMENDED IMMUNIZATION SCHEDULE FOR INFANTS AND CHILDREN.

in their home (Xie & others, 2021). And a recent study found that young children exposed to environmental smoke were more likely to have symptoms of hyperactivity and conduct problems than their counterparts who were not exposed to environmental smoke (Gatzke-Kopp & others, 2019). By driving at safe speeds, decreasing or eliminating drinking (especially before driving), placing children in a car seat correctly, and not smoking around children, caregivers can enhance their children's health and safety (Rojas-Rueda & others, 2021).

Poverty Of special concern in the United States is the poor health of many young children from low-income families. An estimated 7 percent of U.S. children have no usual source of health care. Approximately 11 million preschool children in the United States are malnourished. Their malnutrition places their health at risk. Many have poor resistance to diseases—including minor ones, such as colds, and major ones, such as influenza.

What is the best way to improve the health of children who live in poverty? Some experts argue that offering medical care is not enough (Whitaker & others, 2020). If you give an antibiotic to a child with a sore throat who then returns to a home where she will be cold and hungry, have you provided good health care? One approach to children's health aims to treat not only medical problems of the individual child but also the conditions of the entire family. In fact, some programs seek to identify children who are at risk for problems and then try to alter the risk factors in an effort to prevent illness and disease (Meeks, Heit, & Page, 2020).

There also are persistent ethnic disparities in health coverage and chronic health conditions in U.S. children (Carratala & Maxwell, 2020). For example, in 2017, 7.7 percent of Latinx children were uninsured, compared with 4.1 percent of non-Latinx White children (National Center for Health Statistics, 2018). Also in 2017, 12.6 percent of African American children had asthma, compared with 7.7 percent of non-Latinx White children (National Center for Health Statistics, 2018). Also, Native American and Alaska Native adolescents were 30 percent more likely to be obese than non-Latinx White adolescents (U.S. Department of Health and Human Services Office of Minority Health, 2020).

developmental **connection**
Environment
Poverty is linked to many environmental inequities in childhood. Connect to "Peers and the Sociocultural World."

developmental **connection**
Ethnicity
Ethnic disparities in prenatal care and pregnancy are mainly due to factors linked to socioeconomic status. Connect to "Biological Beginnings."

State of the World's Children Each year UNICEF produces a report titled *The State of the World's Children.* In recent reports, UNICEF (2021) emphasized implications of the under-5 mortality rate of a nation. UNICEF concluded that the under-5 mortality rate reflects a wide range of factors, including the nutritional health and health knowledge of mothers, the level of immunization, dehydration, availability of maternal and child health services, income and food availability in the family, availability of clean water and safe sanitation, and the overall safety of the child's environment.

In countries where poverty rates are high, the effects on children's health are devastating (UNICEF, 2021). People living in poverty are the majority in nearly one of every five nations in the world. They often experience lives of hunger, malnutrition, illness, inadequate access to health care, unsafe water, and a lack of protection from harm (UNICEF, 2021).

In recent decades, there has been a dramatic increase in the number of young children who have died because HIV/AIDS was transmitted to them by their parents (UNICEF, 2021). Deaths of young children due to HIV/AIDS especially occur in countries with high rates of poverty and low levels of education (Stoner & others, 2021). Many of the deaths of young children around the world could be prevented by reducing poverty and improving nutrition, sanitation, education, and health services (UNICEF, 2021).

Many children in impoverished countries die before reaching the age of 5 from dehydration and malnutrition brought about by diarrhea. *What are some of the other main causes of death in young children around the world?*
Bojstudios/Shutterstock

ADOLESCENTS' HEALTH

Adolescence is a critical juncture for adopting behaviors that affect health (Bem & Small, 2020). Many of the factors linked to poor health habits and early death in the adult years begin during adolescence (Taylor, 2021). A special recent concern is the impact of the COVID-19 pandemic on adolescent health care. During the pandemic, some parents avoided taking their children and adolescents to medical facilities for scheduled checkups, new health issues, or emergency care due to fear of contracting the COVID-19 virus. For example, a recent study found that children and adolescents were 70 percent less likely to visit a general hospital emergency department after the pandemic emerged than before it appeared (Goldman & others, 2021). Further, the pandemic raised concerns about increased rates of mental health issues among adolescents, such as anxiety, depression, and suicidal ideation (Magson & others, 2021; Saggioro de Figueiredo & others, 2021).

Social contexts, including families, peers, schools, neighborhoods, and culture, influence adolescent health (Boen, Kozlowski, & Tyson, 2020). Parents and older siblings can serve as important models of health-enhancing behaviors (Burns & others, 2020). In the National Longitudinal Study of Health, which was based on data collected from more than 12,000 seventh- through twelfth-graders, youth who did not eat dinner with a parent five or more days a week had dramatically higher rates of smoking cigarettes, using marijuana, getting into fights, and initiating sexual activity (Council of Economic Advisors, 2000). Parental caring and monitoring often combine to improve health-enhancing behavior and reduce risk taking in youth (Thomson & others, 2020). For example, a recent study found that a higher level of parental monitoring was linked to adolescents' healthier food choices and weight status (Kim & others, 2019).

Peers also can influence adolescents' health. Adolescents who have a limited capacity to resist dares often engage in risk taking at the urging of their peers. Peer pressure can instigate health-compromising behaviors such as cigarette smoking, substance abuse, early sexual activity, and violence (Andrews, Ahmed, & Blakemore, 2021; Prinstein & others, 2018). For example, in a recent study, adolescents with poor-quality friendships in the previous year were more likely to engage in later delinquency (Cho & Galehan, 2020).

Because adolescents spend so much time in school, it is not surprising that what goes on there can influence their health behavior (Boen, Kozlowski, & Tyson, 2020). Teachers, like parents, can serve as important health role models.

Health experts increasingly recognize that whether adolescents will develop a health problem or remain healthy depends primarily on their own behavior. Improving adolescent health involves (1) reducing adolescents' health-compromising behaviors, such as drug abuse, violence, unprotected sexual intercourse, and dangerous driving; and (2) increasing health-enhancing behaviors, such as eating nutritious foods, exercising, and wearing seat belts.

To read about an individual who has made a number of contributions to understanding and improving adolescent health, see the *Connecting with Careers* profile.

connecting with careers

Bonnie Halpern-Felsher, University Professor in Pediatrics and Director of Community Efforts to Improve Adolescents' Health

Dr. Halpern-Felsher recently became a professor in the Department of Pediatrics at Stanford University after holding this position for a number of years at the University of California–San Francisco. Her work exemplifies how some professors not only teach and conduct research in a single discipline such as psychology, but also engage in research in multiple disciplines and work in the community to improve the lives of youth. Dr. Halpern-Felsher is a developmental psychologist with additional training in adolescent health. She is especially interested in understanding why adolescents engage in risk-taking and then using this research to develop intervention programs for improving adolescents' lives.

In particular, Dr. Halpern-Felsher has studied adolescent sexual decision-making and reproductive health, including cognitive and socioemotional predictors of sexual behavior. Her research has included influences of parenting and peer relationships on adolescent sexual behavior. Dr. Halpern-Felsher also has served as a consultant for a number of community-based adolescent health promotion campaigns, and she has been involved in community-based efforts to reduce substance abuse in adolescence. For example, recently she worked with the state of California to implement new school-based tobacco prevention educational materials. As a further indication of her strong commitment to improving adolescents' lives, Dr. Halpern-Felsher coordinates the STEP-UP program (Short-Term Research Experience for Underrepresented Persons) in which she has personally mentored and supervised 22 to 25 middle and high school students every year since 2007.

Dr. Bonnie Halpern-Felsher *(second from left)* with some of the students she is mentoring in the STEP-UP program.

FIGURE **2**

MORTALITY RATES OF U.S. ADOLESCENTS AND EMERGING ADULTS.

EMERGING AND YOUNG ADULTS' HEALTH

Emerging adults have more than twice the mortality rate of adolescents (Park & others, 2008) (see Figure 2). As indicated in Figure 2, males are mainly responsible for the higher mortality rate of emerging adults. Also, compared with adolescents, emerging adults engage in more health-compromising behaviors, have higher rates of chronic health problems, are more likely to be obese, and are more likely to have a mental health disorder (Andraka-Christou & others, 2020).

Why might emerging adults have higher levels of health problems than adolescents do? The likely causes include increased independence, decreased parental monitoring, changing peer/friendship networks, living conditions that provide less support, and increased academic/financial pressures (Hill, 2019).

Although emerging adults may know what it takes to be healthy, they often don't apply this information to their own behavior (Jansen & others, 2021). In many cases, emerging adults are not as healthy as they seem.

In emerging and early adulthood, few individuals stop to think about how their personal lifestyles will affect their health later in their adult lives. As emerging and young adults, many of us develop a pattern of not eating breakfast, not eating regular meals and relying on snacks as our main food source during the day, eating excessively to the point where we exceed the normal weight for our height, smoking moderately or excessively, drinking moderately or excessively, failing to exercise, and getting by with only a few hours of sleep at night (Schiff, 2021). A recent study of college students revealed that regularly eating breakfast was positively linked to their grade point average (GPA), while regularly eating fast food was negatively associated with their GPA (Reuter, Forster, & Brister, 2021). These lifestyles are associated with poor health, which in turn impairs life satisfaction (Fahey, Insel, & Roth, 2021). In some cases, unhealthy behavior increases as individuals go through college. For example, a study found that rates of being overweight or obese increased from 25.6 percent for college freshmen to 32 percent for college seniors (Nicoteri & Miskovsky, 2014). Also, in the Berkeley Longitudinal Study—in which individuals were evaluated over a period of 40 years—physical health at age 30 predicted life satisfaction at age 70, more so for men than for women (Mussen, Honzik, & Eichorn, 1982).

By the time individuals reach early adulthood, ethnic disparities characterize their health (Carratala & Maxwell, 2020). For example, in 2016, among U.S. adults 20 years and older, 47.5 percent of African Americans were obese, closely followed by Latinx adults at 46.9 percent (compared with 38.2 percent of non-Latinx Whites and only 12.4 percent of Asian Americans) (Health United States, 2019). Also, in 2016, 42.1 percent of African American adults 20 years and older had hypertension, compared with 29.4 percent of Latinxs, 28.7 percent of non-Latinx Whites, and 27.2 percent of Asian Americans.

HEALTH AND AGING

Aging can bring new health problems, such as Alzheimer disease. Keep in mind, though, that many older adults are healthy (Henning-Smith, 2020). For example, only 17 percent of U.S. adults from 65 to 74 years of age have a disability. As shown in Figure 3, the percentage of older Americans who have a disability remains below 50 percent until they reach 85 years and older.

Chronic Disorders

Chronic disorders are characterized by a slow onset and long duration (Sanchez, 2021). Chronic disorders are rare in early adulthood, increase in middle adulthood, and become common in late adulthood (Ibrahim, Aitken, & Ransom, 2021).

chronic disorders Disorders characterized by slow onset and long duration.

The most common chronic disorders differ for females and males (Karolyi & others, 2021; Shlyakhto, 2018). Arthritis is the most common chronic disorder in late adulthood, followed

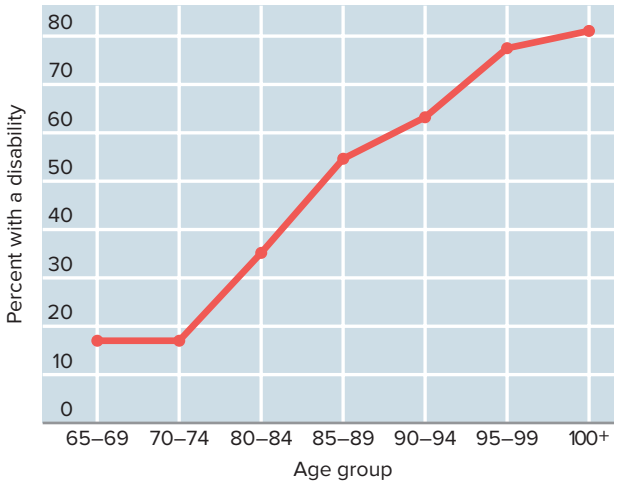
by hypertension. Older women have a higher incidence of arthritis, hypertension, and visual problems but a lower incidence of hearing problems than older men do.

Even when adults over the age of 65 have a physical impairment, though, many of them can still carry on their everyday activities or work. Chronic conditions associated with the greatest limitation on work are heart conditions (52 percent), diabetes (34 percent), asthma (27 percent), and arthritis (27 percent).

Arthritis—an inflammation of the joints accompanied by pain, stiffness, and movement problems—is the most common chronic disorder in older adults (Subedi & others, 2020). There is no known cure for arthritis, but the symptoms can be treated with drugs such as aspirin and acetaminophen, range-of-motion exercises, weight reduction, and in extreme cases, replacement of the crippled joint with a prosthesis (Arden & others, 2021). Recent research has documented the benefits of exercise for older adults with arthritis (Azeez & others, 2020; Whittaker & others, 2021).

Normal aging involves some loss of bone tissue from the skeleton. However, in some instances loss of bone tissue can become severe. **Osteoporosis** involves an extensive loss of bone tissue. Osteoporosis is the main reason many older adults walk with a marked stoop (Falaschi, Marques, & Giordano, 2021). Women are especially vulnerable to osteoporosis, which is the leading cause of broken bones in women (Bhattarai & others, 2020). Approximately 80 percent of osteoporosis cases in the United States occur in females, 20 percent in males. Almost two-thirds of all women over the age of 60 are affected by osteoporosis. This aging disorder is most common in non-Latina White, thin, and small-framed women.

Osteoporosis is related to deficiencies in calcium, vitamin D, and estrogen, as well as lack of exercise (Pan & others, 2020). To prevent osteoporosis, young and middle-aged women should eat foods rich in calcium, exercise regularly, and avoid smoking (Kistler-Fischbacher, Weeks, & Beck, 2021). A recent Swiss study indicated that postmenopausal women consume high amounts of vegetables but insufficient calcium and dairy products (Lanyan & others, 2020). Drugs such as Fosamax can be used to prevent or treat osteoporosis in postmenopausal women (Curtis & others, 2020).



Note: Data for the 75 to 79 age group were unavailable.

FIGURE 3

What characterizes osteoporosis? What are some strategies for reducing the severity of osteoporosis?
Apple Tree House/Photodisc/Getty Images

Causes of Death in Older Adults Nearly 60 percent of deaths among U.S. adults 65 to 74 years of age are caused by cancer or cardiovascular disease (Center for Health Statistics, 2018). Cancer has replaced cardiovascular disease as the leading cause of death in U.S. middle-aged adults (Heron, 2013). The same realignment of causes of death has also occurred in 65- to 74-year-olds, with cancer now the leading cause of death in this age group (Center for Health Statistics, 2018). The decline in cardiovascular disease in middle-aged and older adults has been attributed to improved drugs, decreased rates of smoking, improved diets, and increased exercise (Jefferson, Demasi, & Doshi, 2020).

However, in the 75-to-84 and 85-and-over age groups, cardiovascular disease still is the leading cause of death (Center for Health Statistics, 2020a). As individuals age during the period of late adulthood, they become more likely to die from cardiovascular disease than from cancer.

In 2020, a number of older adults died because of the coronavirus pandemic. Eight of ten COVID-19 deaths in the United States have occurred in adults 65 years and older (Centers for Disease Control and Prevention, 2020b). Older individuals who are at the greatest risk for getting the virus and dying are in the 85-and-older age group. Many older adults who have COVID-19 also have underlying conditions that increase their risk of dying from the virus, such as cardiovascular disease. Also, the older an individual is, the less effective their immune system is in combatting the virus.

Health problems that accompany aging also can involve neurological disorders. Next, we examine a neurological disorder in aging that has dramatically increased in recent decades—Alzheimer disease, which accounts for an increasing number of deaths in late adulthood.

osteoporosis A disorder that involves an extensive loss of bone tissue and is the main reason many older adults walk with a marked stoop. Women are especially vulnerable to osteoporosis.

Alzheimer Disease

Dementia is a global term for several neurological disorders involving a nonreversible decline in mental function severe enough to interfere with daily life (Ghneim & Diaz, 2021; Swift & others, 2021). Alzheimer disease accounts for 60 to 80 percent of dementias, with the second most frequent being vascular dementia. In a recent Chinese study, medium to high physical activity was linked a lower incidence of dementia in 60- to 65-year-olds (Wu & others, 2020).

The most common form of dementia is **Alzheimer disease**—a progressive, irreversible brain disorder that is characterized by a gradual deterioration of memory, reasoning, language, and eventually, physical function. In 2020, an estimated 5.8 million adults in the United States had Alzheimer disease, and it has been projected that 10 million baby boomers will develop Alzheimer disease in their lifetime (Alzheimer's Association, 2020). Ten percent of individuals 65 and older have Alzheimer disease. The percentage of individuals with Alzheimer disease increases dramatically with age: 3 percent aged 65 to 74, 17 percent aged 75 to 84, and 32 percent aged 85 and older (Alzheimer's Association, 2020).

Gender and ethnic variations occur in Alzheimer disease. Two-thirds of those with Alzheimer disease in the United States are women (Alzheimer's Association, 2020). Women are more likely than men to develop Alzheimer disease because their longer life expectancy increases the number of years during which they can develop it. African Americans are twice as likely and Latinxs one and one-half times as likely as non-Latinx Whites to have Alzheimer disease (Alzheimer's Association, 2020). The reasons for these ethnic discrepancies mainly involve other medical conditions and socioeconomic status factors such as education and income. It is estimated that Alzheimer disease triples the healthcare costs of Americans 65 years of age and older (Alzheimer's Association, 2020). Because of the increasing prevalence of Alzheimer disease, researchers have stepped up their efforts to discover the causes of the disease and to find more effective ways to treat it (Cummings, 2021).

dementia A global term for several neurological disorders involving a nonreversible decline in mental function severe enough to interfere with daily life.

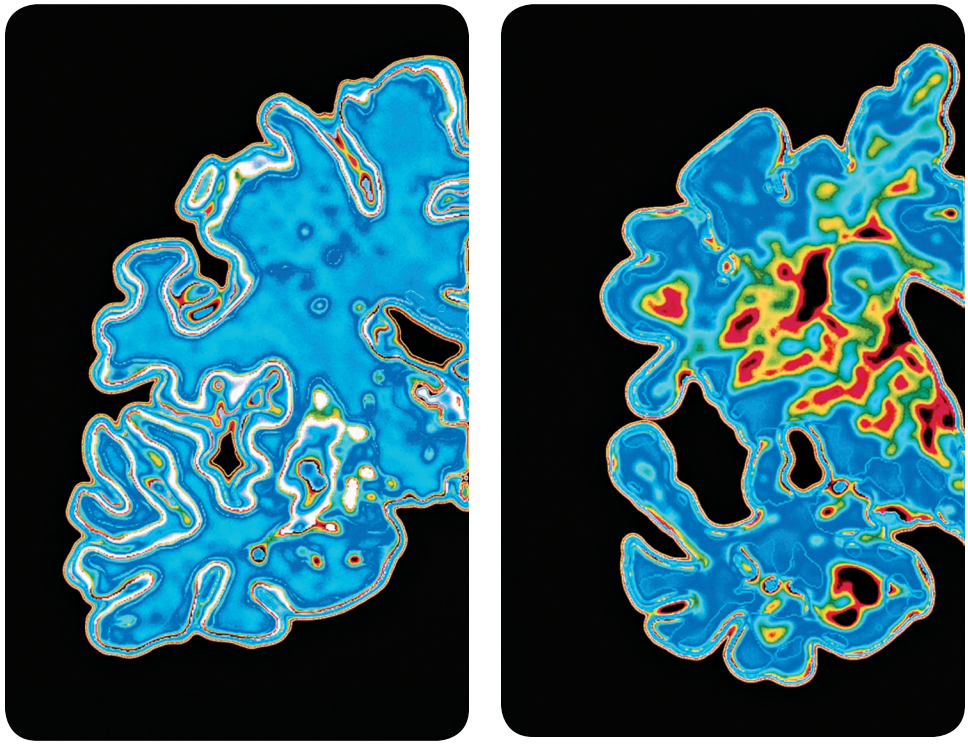
Alzheimer disease A progressive, irreversible brain disorder characterized by a gradual deterioration of memory, reasoning, language, and eventually, physical function.

Causes

Alzheimer disease involves a deficiency in the brain messenger chemical acetylcholine, which plays an important role in memory (Barter & Foster, 2020). Also, as Alzheimer disease progresses, the brain shrinks and deteriorates (see Figure 4). This deterioration is characterized by the formation of *amyloid plaques* (dense deposits of protein that accumulate in the blood vessels) (Lin & others, 2020) and *neurofibrillary tangles* (twisted fibers that build

FIGURE **4**

TWO BRAINS: NORMAL AGING AND ALZHEIMER DISEASE. The computer graphic on the left shows a slice of a normal aging brain, while the photograph on the right shows a slice of a brain ravaged by Alzheimer disease. Notice the deterioration and shrinking in the diseased brain.
Alfred Pasieka/Science Source



up in neurons) (Sharma, Mehta, & Singh, 2020). Neurofibrillary tangles consist mainly of a protein called *tau* (Kim & Park, 2020). Currently, there is considerable research interest in the roles that amyloid plaques and tau play in Alzheimer disease (Gonzalez-Escamilla & others, 2021).

There is increasing interest in the role that oxidative stress might play in the development of Alzheimer disease (Mi & others, 2021). Oxidative stress occurs when the body's antioxidant defenses are unable to cope with free-radical attacks and oxidation in the body (Jurcau & Simon, 2020). Recall from the chapter on "Physical Development and Aging" that free-radical theory is one of the major explanations of the aging process. Further, mitochondrial dysfunction is an early event in Alzheimer disease (Yang & others, 2020).

Although scientists have not identified the specific causes of Alzheimer disease, age is an important risk factor and genes also are likely to play a significant role (Sims, Hill, & Williams, 2020). The number of individuals with Alzheimer disease doubles every five years after the age of 65. A gene called *apolipoprotein E* (*ApoE*) is linked to an increasing presence of plaques and tangles in the brain (Minta & others, 2020). Special attention has focused on the presence of an allele (an alternative form of a gene) labeled ApoE4 that has been identified as a strong risk factor for Alzheimer disease (Montagne, Nation, & Ziokovic, 2020). More than 60 percent of individuals with Alzheimer disease have at least one ApoE4 allele (Dubal & Rogine, 2017). Also, women are more likely than men to have the ApoE4 gene (Dubal & Rogine, 2017). Further, the ApoE2 allele is the strongest genetic protective factor for Alzheimer disease (Serrano-Pozo, Das, & Hyman, 2021).

Although individuals with a family history of Alzheimer disease are at greater risk than the general population, the disease is complex and likely to be caused by a number of factors, including lifestyle choices (Ettcheto & others, 2020). Recently there has been increasing interest in how epigenetics may improve understanding of Alzheimer disease (Alcala-Vida & others, 2021; Mahajan & others, 2020). This interest especially has focused on DNA methylation, which we discussed in "Biological Beginnings." Recall that DNA methylation involves tiny atoms attaching themselves to the outside of a gene, a process that is increased through exercise and healthy diet but reduced by tobacco use (Dasinger & others, 2020). Further, recent research indicated that ApoE4 and ApoE2 alleles were associated with methylation differences in the blood, especially in lipid and cholesterol processes (Walker & others, 2021). Thus, lifestyles likely interact with genes to influence Alzheimer disease.

Recently, many cardiac risk factors, such as obesity, smoking, atherosclerosis, high cholesterol, and lipids, also have been implicated in Alzheimer disease (Jiang & others, 2020; Leszek & others, 2021). One of the best strategies for preventing or delaying the onset of Alzheimer disease in people who are at risk is to improve their cardiac functioning through diet, drugs, and exercise (Zhou & others, 2020).

developmental **connection**

Memory

A number of changes in memory occur in late adulthood. Connect to "Information Processing."

Early Detection *Mild cognitive impairment* (*MCI*) represents a transitional state between the cognitive changes of normal aging and very early stages of Alzheimer disease and other dementias (Lissek & Suchan, 2021). MCI is increasingly recognized as a risk factor for Alzheimer disease. It is estimated that as many as 10 to 20 percent of individuals 65 years of age and older have MCI (Alzheimer's Association, 2020). Some individuals with MCI do not go on to develop Alzheimer disease, but MCI is a risk factor for Alzheimer disease (Liu & others, 2020).

Distinguishing between individuals who merely have age-associated declines in memory and those with MCI is difficult, as is predicting which individuals with MCI will subsequently develop Alzheimer disease (Bradfield & others, 2021; Xu & others, 2020). One study revealed that individuals with mild cognitive impairment who developed Alzheimer disease had at least one copy of the ApoE4 allele (Alegret & others, 2014). In this study, the extent of memory impairment was the key factor linked to the speed of decline from mild cognitive impairment to Alzheimer disease. Further, a recent research review concluded that combined cognitive and physical interventions can improve cognitive (executive

Memory loss is a common characteristic of Alzheimer disease. Written reminders can help individuals with Alzheimer remember daily tasks.

©Ray Chavez/MCT/Landov

function and memory, for example) and physical function (mobility and balance, for example) in individuals with mild cognitive impairment (Yang & others, 2020).

Drug Treatment of Alzheimer Disease Five drugs have been approved by the U.S. Food and Drug Administration (FDA) for the treatment of Alzheimer disease (Almeida, 2018). Three of the medications, Aricept (donepezil), Razadyne (galantamine), and Exelon (rivastigmine), are cholinesterase inhibitors designed to improve memory and other cognitive functions by increasing levels of acetylcholine in the brain (Gareri & others, 2017). Keep in mind that the current drugs used to treat Alzheimer disease only slow the downward progression of the disease; they do not address its cause (Cummings, 2021). However, an extensive research effort is underway to discover drugs that will slow this downward progression, especially drugs that can decrease or remove plaques and tangles (Zetterberg & Bendlin, 2021). Also, no drugs have yet been approved by the Food and Drug Administration (FDA) for the treatment of MCI (Alzheimer's Association, 2020).

Caring for Individuals with Alzheimer Disease A special concern is the stress involved in caring for Alzheimer patients (Alzheimer's Association, 2020). In the United States, 50 percent of the care given to older adults is for individuals with Alzheimer disease (Alzheimer's Association, 2020). Health-care professionals emphasize that the family can be an important support system for the Alzheimer patient, but this support can have costs for family members who become emotionally and physically drained from providing the extensive care required for a person with Alzheimer disease (Greenberg, Wallick, & Brown, 2020).

Respite care (services that provide temporary relief for those who are caring for individuals with disabilities or illnesses) can ease the stress experienced by people who have to meet the day-to-day needs of Alzheimer patients (Feldman & others, 2021). This type of care provides an important break from the burden of providing chronic care (Blater, 2020). To read further about individuals who care for Alzheimer patients, see the *Connecting with Research* interlude.

Muhammad Ali, who was one of the world's leading sports figures, had Parkinson disease.
AP Images

Parkinson Disease

Another type of dementia is **Parkinson disease,** a chronic, progressive disorder characterized by muscle tremors, slowing of movement, and partial facial paralysis. Parkinson disease is triggered by degeneration of dopamine-producing neurons in the brain (Oh & others, 2020). Dopamine is a neurotransmitter that is necessary for normal brain functioning. Why these neurons degenerate is not known.

The main treatment for Parkinson disease involves administering drugs that enhance the effect of dopamine (dopamine agonists) in the disease's earlier stages and later administering the drug L-dopa, which is converted by the brain into dopamine (Pingale & Lal Gupta, 2021). However, it is difficult to determine the correct dosage of L-dopa, and it loses its efficacy over time. Another treatment for advanced Parkinson disease is deep brain stimulation (DBS), which involves implanting electrodes in the brain. The electrodes are then stimulated by a pacemaker-like device. A recent research review concluded that DBS improves motor function for up to 10 years in Parkinson patients, but improvement tends to decline over time (Limousin & Foltynie, 2019). Stem cell transplantation and gene therapy offer hope for the future in treating Parkinson disease (Xiong & others, 2021).

Parkinson disease A chronic, progressive disease characterized by muscle tremors, slowing of movement, and partial facial paralysis.

Health Treatment for Older Adults

The development of alternative forms of home and community-based care has decreased the percentage of older adults who are living in nursing homes (Ranucci & Berry, 2021). Still, as older adults age, their probability of being in a nursing home increases (see Figure 6). What is the quality of nursing homes and extended-care facilities for older adults? What is the relationship between older adults and health-care providers?

The coronavirus pandemic in 2020 raised special concerns about nursing homes (Abrams & others, 2020; Konetzka & Gorges, 2021). As of July 1, 2020, nursing home and assisted living facilities accounted for 43 percent of deaths caused by COVID-19. Problems caused by inadequate funding and inconsistent quality control in nursing homes predate COVID-19 and continue to be a major focus of national concern.

How Stressful is Caring for an Alzheimer Patient at Home?

Courtesy Janice Kiecolt-Glaser

Janice Kiecolt-Glaser

Key Points:

- caring for Alzheimer patients at home
- immune system of caregivers
- increased stress levels and likely increase in illness and disease

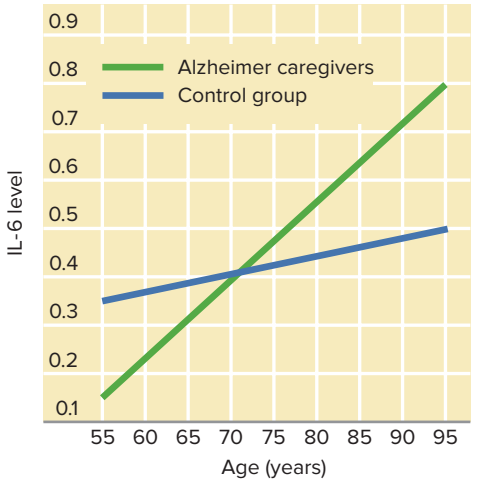

FIGURE 5

COMPARISON OF IL-6 LEVELS IN ALZHEIMER CAREGIVERS AND A CONTROL GROUP OF NONCAREGIVERS. Notice that IL-6 (an immune chemical that places individuals at risk for a number of diseases) increased for both the Alzheimer caregivers and a control group of noncaregivers. However, also note that IL-6 increased significantly more in the Alzheimer caregivers. A higher score for IL-6 reflects a higher level of the immune chemical.

Researchers have found that the stress of caring for an Alzheimer patient at home can prematurely age the immune system, putting caregivers at risk for developing age-related diseases (Glaser & Kiecolt-Glaser, 2005; Kiecolt-Glaser & Wilson, 2017; Wilson & others, 2019). In one study, 119 older adults who were caring for a spouse with Alzheimer disease or another form of dementia (which can require up to 100 hours a week) were compared with 106 older adults who did not have to care for a chronically ill spouse (Kiecolt-Glazer & others, 2003). The age of the older adults upon entry into the study ranged from 55 to 89, with an average age of 70.

Periodically during the six-year study, blood samples were taken and the levels of a naturally produced immune chemical called interleukin-6, or IL-6, were measured. IL-6 increases with age and can place people at risk for a number of illnesses, including cardiovascular disease, type 2 diabetes, frailty, and certain cancers. The researchers found that the levels of IL-6 increased much faster in the Alzheimer caregivers than in the older adults who did not have to care for a critically ill spouse (see Figure 5).

Each time IL-6 was assessed by drawing blood, the participants also completed a 10-item perceived stress scale to assess the extent to which they perceived their daily life during the prior week as being "unpredictable, uncontrollable, and overloading" (Kiecolt-Glazer & others, 2003, p. 90–91). Participants rated each item from 0 (never) to 4 (very often). Alzheimer caregivers reported greater stress than the noncaregiver controls across each of the six annual assessments.

Since family members are especially important in helping Alzheimer patients cope, an important research agenda is to assess the benefits of respite care and to find additional ways to relieve the stress the disease can impose on others.

What kinds of studies might help provide some answers? What challenges will researchers face in collecting data?

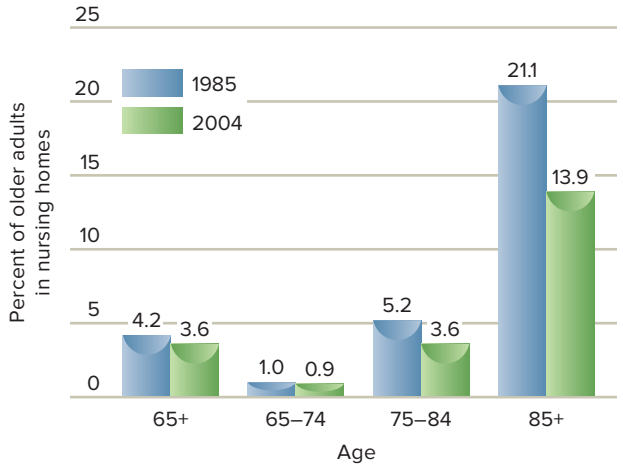

FIGURE 6

PERCENT OF U.S. OLDER ADULTS LIVING IN NURSING HOMES: 1985 TO 2004. *Note*: The calculations are based on the 1985 and 2004 National Nursing Home Survey (NNHS), National Center for Health Statistics.

More than 40 percent of the COVID-19 deaths in the United States through June 2020 occurred in nursing homes and assisted living facilities. In the Elmhurst neighborhood of the Queens borough of New York City, so many deaths were occurring so quickly that bodies had to be stored temporarily in a chapel and then loaded onto trucks (shown here) to be transported to crematoriums and cemeteries.
Andrew Lichtenstein/Getty Images

The quality of nursing homes and other extended-care facilities for older adults varies enormously and is a source of ongoing concern (He, Li, & Fang, 2020). More than one-third of these facilities are seriously deficient. They fail federally mandated inspections because they do not meet the minimum standards for physicians, pharmacists, and various rehabilitation specialists (occupational and physical therapists). Further concerns focus on lack of expertise among some nursing home professionals, protecting patients' right to privacy, providing access to medical information, preventing inappropriate prescriptions, poor patient surveillance, ensuring safety, and preserving lifestyle freedom within the individual's range of mental and physical capabilities (Aschien, Barello, & Durosini, 2021).

Because of the inadequate quality of many nursing homes and the escalating costs for nursing home care, many specialists in the health problems of the aged stress that home health care, elder-care centers, and preventive medicine clinics are good alternatives (Sood & Walker, 2020). They are potentially less expensive than hospitals and nursing homes. They also are less likely to engender the feelings of depersonalization and dependency that occur so often in residents of institutions. Currently, there is an increased demand for home-care workers because of the expanding population of older adults and their preference to stay in their own homes (Ranucci & Berry, 2021). In a study of elderly adults with cognitive impairment, those who were cared for at home were less depressed, had better cognitive functioning, and reported a higher level of social connectedness than their counterparts who were in formal institutional care (Nikmat, Al-Mashoor, & Hashim, 2015).

In a classic study that focused on the way older adults are cared for in nursing homes, Judith Rodin and Ellen Langer (1977) found that an important factor related to health, and even survival, in a nursing home is the patient's feelings of control and self-determination. A group of elderly nursing home residents were encouraged to make more day-to-day choices and thus feel they had greater control over their lives. They began to decide such matters as what they ate, when their visitors could come, what movies they saw, and who could come to their rooms. A similar group in the same nursing home was told by the administrator how caring the nursing home was and how much the staff wanted to help, but these elderly nursing home residents were given no opportunities to take more control over their lives. Eighteen months later, the residents who had been given responsibility and control were more alert and active, and said they were happier, than the residents who had been encouraged only to feel that the staff would try to satisfy their needs. And the "responsible" or "self-control" group had significantly better improvement in their health than did the "dependent" group. Even more important was the finding that after 18 months only half as many nursing home residents in the "responsibility" group had died as in the "dependent" group (see Figure 7). Perceived control over one's environment, then, can literally be a matter of life or death.

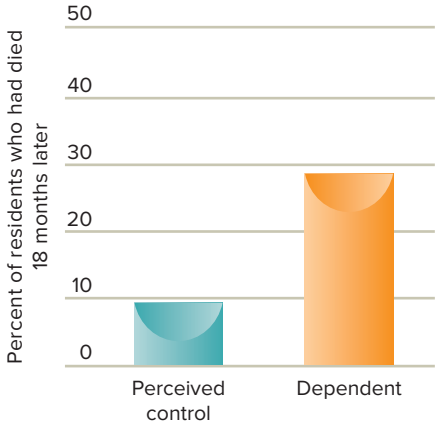

FIGURE 7

PERCEIVED CONTROL AND MORTALITY. In the study by Rodin and Langer (1977), nursing home residents who were encouraged to feel more in control of their lives were more likely to be alive 18 months later than those who were treated as being more dependent on the nursing home staff.

2 Nutrition and Eating Behavior

LG2 Characterize developmental changes in nutrition and eating behavior.

Infancy | Childhood | Adolescence | Adult Development and Aging

Nutritional needs, eating behavior, and related issues vary to some extent across the life span. Let's begin by exploring what takes place with infants.

INFANCY

For infants, the importance of receiving adequate energy intake and nutrients in a loving and supportive environment cannot be overstated (Schiff, 2022). From birth to 1 year of age, human infants triple their weight and increase their length by 50 percent. Because infants vary in their nutrient reserves, body composition, growth rates, and activity patterns, their nutrient needs vary as well. However, because parents need guidelines, nutritionists recommend that infants consume approximately 50 calories per day for each pound they weigh—more than twice an adult's requirement per pound.

Caregivers play very important roles in infants' and young children's development of eating patterns (Mennella & others, 2021). Caregivers who are not sensitive to developmental changes in infants' nutritional needs, neglectful caregivers, and conditions of poverty can contribute to the development of eating problems in infants. Too many young children also already have developed a pattern of not eating enough fruits and vegetables, a pattern that can have negative consequences later in development (Byrd-Bredbenner, Berning, & Kelley, 2022). For example, a recent study revealed that 2½-year-old children's liking for fruits and vegetables was related to their eating more fruits and vegetables at 7 years of age (Fletcher & others, 2017).

In addition to good nutrition, children need a nurturing, supportive environment (Schiff, 2021). One individual who has stood out as an advocate of caring for children and who has been especially passionate about preventing child obesity is pediatrician Faize Mustafa-Infante, who is featured in *Connecting with Careers*.

Breast Versus Bottle Feeding For the first four to six months of life, human milk or an alternative formula is the baby's source of nutrients and energy. For years, debate has focused on whether breast feeding is better for the infant than bottle feeding. The growing consensus is that breast feeding is better for the baby's health (Blake, 2020). Since the 1970s, breast feeding by U.S. mothers has soared (see Figure 8). In 2017, 84.1 percent of U.S. mothers breast fed their newborns, and 58.3 percent breast fed their 6-month-olds (Centers for Disease Control and Prevention, 2020). The American Academy of Pediatrics Section on Breastfeeding (2012) reconfirmed its recommendation of exclusive breast feeding in the first

connecting with careers

Dr. Faize Mustafa-Infante, Pediatrician

Dr. Mustafa-Infante grew up in Colombia, South America. After completing her undergraduate education she taught elementary school students in Colombia for several years and then returned to college to obtain her medical degree with a specialty in pediatrics. Once she finished her medical training, she moved to San Bernardino, California, where she worked as a health educator with a focus on preventing and treating childhood obesity in low-income communities.

Dr. Mustafa-Infante currently works at Mission Pediatrics in Riverside, California, where she mainly treats infants. She has continued striving to prevent obesity in children and also serves as a volunteer for Ayacucho Mission, a nonprofit organization that provides culturally sensitive medical care for people living in poverty in Ayacucho, Peru.

In regard to her cultural background, Dr. Mustafa-Infante describes herself as a Latina doctor with a Middle-Eastern name that reflects her strong family commitments to both heritages. Dr. Mustafa-Infante says that hard work and education have been the keys to her success and personal satisfaction.

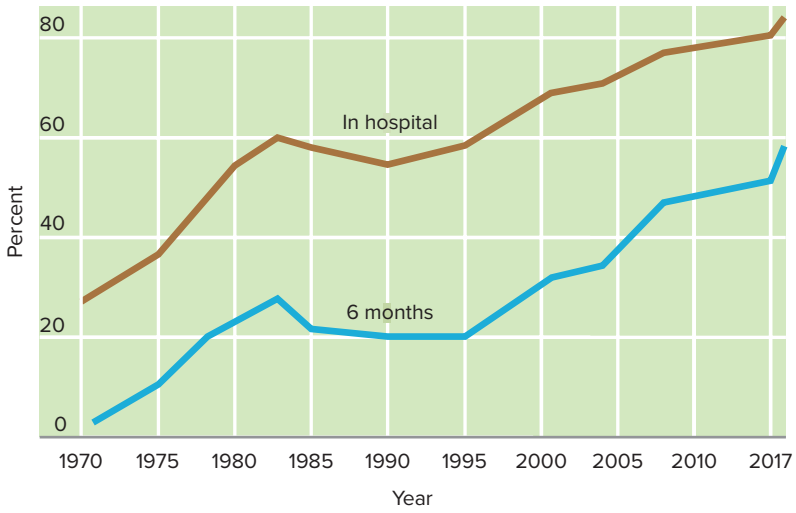

FIGURE **8**

TRENDS IN BREAST FEEDING IN THE UNITED STATES: 1970–2017.

six months followed by continued breast feeding as complementary foods are introduced, with further breast feeding for one year or longer as mutually desired by the mother and infant.

Outcomes of Breast Feeding for Children What are some of the benefits of breast feeding for children, based on research?

- *Gastrointestinal infections*. Breast-fed infants have fewer gastrointestinal infections (Bartick & others, 2017).
- *Respiratory tract infections*. Breast-fed infants have fewer infections of the lower respiratory tract (Bartick & others, 2017).
- *Allergies*. A recent research review found no evidence that breast feeding reduces the risk of allergies in young children (Vandenplas & others, 2021).
- *Asthma*. Exclusive breast feeding for three months protects against wheezing in babies, but whether it prevents asthma in older children is unclear (Greer & others, 2008; Wang & others, 2017).
- *Otitis media*. Breast-fed infants are less likely to develop this middle ear infection (Pelton & Leibovitz, 2009).
- *Immune system.* Breast-fed infants have a more effective immune system for fighting off disease (Nolan, Parks, & Good, 2019).
- *Fever.* Breast-fed infants are less likely to develop a fever in the first six months of their lives (Saeed, Haile, & Chertok, 2020).
- *Overweight and obesity*. Consistent evidence indicates that breast-fed infants are less likely to become overweight or obese in childhood, adolescence, and adulthood (Ma & others, 2020).
- *Dietary intake*. Few studies have examined links between breast feeding and later dietary intake, although a recent study found that breast feeding was associated with greater vegetable intake and avoidance of sugar-sweetened beverages in childhood but not in adolescence (Kheir & others, 2021).
- *Cardiovascular system*. Individuals who were breast fed as infants have higher cardiovascular fitness in childhood and adolescence (4 to 18 years of age) (Berlanga-Macias & others, 2020).
- *Diabetes*. Breast-fed infants are less likely to develop type 1 diabetes in childhood (Ping & Hagopian, 2006) and type 2 diabetes in adulthood (Villegas & others, 2008).
- *SIDS*. Breast-fed infants are less likely to experience SIDS (Cowgill, 2020).
- *Hospitalization*. Recent research found that breast-fed infants had lower rates of hospitalization for a number of conditions, including gastrointestinal problems and lower respiratory tract infections (Bartick & others, 2017).

developmental **connection**

Conditions, Diseases, and Disorders

What characterizes SIDS? Connect to "Physical Development and Biological Aging."

A large-scale research review found no conclusive evidence that breast feeding improves children's cognitive development and cardiovascular functioning (Agency for Healthcare Research and Quality, 2007; Ip & others, 2009).

Outcomes of Breast Feeding for the Mother What are the outcomes of breast feeding for the mother, based on research? Recently, the American College of Obstetricians and Gynecologists (ACOG) summarized research on outcomes of breast feeding for the mother:

- *Breast cancer*. Consistent evidence indicates a lower incidence of breast cancer in women who breast feed their infants (ACOG, 2021).
- *Ovarian cancer*. Evidence also reveals a reduction in ovarian cancer in women who breast feed their infants (ACOG, 2021).
- *Type 2 diabetes*. Evidence suggests reduced rates of type 2 diabetes in women who breast feed their infants (ACOG, 2021).

- *Hypertensive cardiovascular disease.* Research indicates that women who breast feed are at a lower risk for cardiovascular disease linked to high blood pressure (ACOG, 2021).
- *Hospitalization*. Research has found that mothers who breast fed their babies have lower rates of hospitalization for cardiovascular problems and diabetes (Bartick & others, 2017).

Large-scale research reviews found no conclusive evidence that breast feeding accelerates the mother's return to prepregnancy weight, prevents osteoporosis, or prevents postpartum depression (Agency for Healthcare Research and Quality, 2007; Ip & others, 2009).

As mentioned previously, the American Academy of Pediatrics Section on Breastfeeding (2012) strongly endorses exclusive breast feeding through six months and further recommends breast feeding for another year. Are there circumstances when mothers should not breast feed? Yes, a mother should not breast feed (1) if she has HIV or some other infectious disease that can be transmitted through her milk; (2) if she has active tuberculosis; or (3) if she is taking any drug that may not be safe for the infant (Remmert & others, 2020).

Some women cannot breast feed their infants because of physical difficulties; others feel guilty if they terminate breast feeding early. Mothers may also worry that they are depriving their infants of important emotional and psychological benefits if they bottle feed rather than breast feed. Some researchers have found, however, that there are no psychological differences between breast-fed and bottle-fed infants (Fergusson, Horwood, & Shannon, 1987; Young, 1990).

A further issue in interpreting the benefits of breast feeding was underscored in a large-scale research review (Ip & others, 2009). While highlighting a number of breast feeding benefits for children and mothers, the report issued a caution about breast feeding research: None of the findings implies causality. Breast versus bottle feeding studies are correlational, not experimental, and women who breast feed tend to be wealthier, older, more educated, and likely more health-conscious than their bottle feeding counterparts—characteristics that could explain why breast-fed children are healthier.

CHILDHOOD

Eating habits are important aspects of development during early childhood (Donatelle & Ketcham, 2020). What children eat affects their skeletal growth, body shape, and susceptibility to disease. In a recent national study, dietary quality of U.S. children decreased from 6 months of age to 4 years of age (Hamner & Moore, 2020).

Malnutrition continues to be a major threat to millions of children (Schiff, 2022). Malnutrition and starvation are a daily fact of life for children in many developing countries (Skouteris & others, 2021; UNICEF, 2021).

Poor nutrition also is a special concern in the lives of infants and children from low-income families in the United States. To address this problem, the WIC (Women, Infants, and Children) program provides federal grants to states for healthy supplemental foods, health-care referrals, and nutrition education for women from low-income families beginning in pregnancy, and to infants and young children up to 5 years of age who are at nutritional risk (Xuemei & others, 2021). WIC serves approximately 7,500,000 participants in the United States. Positive outcomes have been documented for participation in the WIC program (Anderson & others, 2020). For example, in a recent study, high-risk infants in a WIC program had higher cognitive scores on the Bayley Scales of Infant Development (Lakshmanan & others, 2020).

A special concern for low-income families recently emerged as the spread of COVID-19 in the United States led most states to close or extensively limit their early child care and education programs (Bauer & others, 2021). These closures affected many of the 4.6 million low-income young children who had been receiving free meals and snacks each day.

Human milk or an alternative formula is a baby's source of nutrients for the first four to six months. The growing consensus is that breast feeding is better than bottle feeding for the baby's health, although controversy still surrounds the issue of breast feeding versus bottle feeding. *Why is breast feeding strongly recommended by pediatricians?*
JGI/Blend Images/Blend Images/Getty Images

Overweight Children Being overweight has become a serious health problem in childhood (Insel & Roth, 2022). Exemplifying the eating habits of young children that contribute to being overweight, a study of U.S. 2- and 3-year-olds found that French fries and other fried potatoes were the vegetable they were most likely to consume (Fox & others, 2010). A survey of 34 countries revealed that the United States had the second highest rate of childhood obesity (Janssen & others, 2005).

The Centers for Disease Control and Prevention (2021) has established categories for obesity, overweight, and at risk of being overweight. These categories are determined by body

What are some trends in the eating habits and weight of young children?
Jamie Grill/Getty Images

mass index (BMI), which is computed by a formula that takes into account height and weight. Children and adolescents whose BMI is at or above the 97th percentile are classified as obese; those whose BMI is at or above the 95th percentile are overweight; and those whose BMI is at or above the 85th percentile are at risk of becoming overweight.

The percentages of young children who are overweight or at risk of being overweight in the United States have increased dramatically in recent decades (Schiff, 2021). In 2009–2010, 12.1 percent of U.S. 2- to 5-year-olds were classified as obese, compared with 5 percent in 1976–1980 and 10.4 percent in 2007–2008 (Ogden & others, 2012). In 2015–2016, 13.9 percent of 2- to 5-year-olds were obese. Also, more children are overweight in middle and late childhood than in early childhood. In 2015–2016, 18.4 percent of 6- to 11-year-old U.S. children were classified as obese, an increase of one percent since 2009–2010 (Hales & others, 2017).

Concern about overweight and obesity in childhood extends beyond the borders of the United States. According to the World Health Organization (2020), 38 million children under the age of 5 years were overweight or obese around the world in 2019. Further, more than 340 million children and adolescents aged 5 to 19 were overweight or obese worldwide in 2016.

If people are overweight or obese as young children, their likelihood of being overweight or obese in adolescence and adulthood increases dramatically. For example, in one U.S. study, overweight 5-year-olds were four times more likely to be obese at 14 years of age than their counterparts who began kindergarten at a normal weight (Cunningham, Kramer, & Narayan, 2014). Also, in another study, preschool children who were obese were five times more likely to be overweight or obese as adults (Ogden & others, 2014).

Consequences of Obesity The increasing number of overweight children in recent decades is cause for great concern, because being overweight raises the risk for many medical and psychological problems (Thavamani & others, 2020). Overweight children are at risk for developing pulmonary problems such as sleep apnea (which involves upper-airway obstruction), and for having hip problems (Andersen, Holm, & Homoe, 2019). Type 2 diabetes, hypertension (high blood pressure), and elevated blood cholesterol levels also are common in children who are overweight (Liang & others, 2020; Villasis-Keever & others, 2021). Further, a recent Chinese study found that children and adolescents who were obese were more likely to have depression and anxiety symptoms than non-obese children and adolescents (Wang & others, 2019). And a recent research review concluded that obesity is linked with low self-esteem in children (Moharei & others, 2018).

Dana Hoff/Getty Images

Treatment of Obesity A combination of diet, exercise, and behavior modification is often recommended to help children lose weight (Lumpkin, 2021). Intervention programs that emphasize getting parents to engage in more healthful lifestyles themselves, as well as to feed their children healthy foods and get them to exercise more, can produce weight reduction in overweight and obese children. A recent study found that positive parenting that emphasized praise for healthy eating behavior improved young children's eating behavior (increased vegetable intake, for example) and helped overweight children lose weight better than negative comments by parents did (Rotman & others, 2020).

Too much screen time is linked to young children's risk of becoming overweight or obese. Recently, the World Health Organization (WHO) recommended that 3- to 4-year-olds should engage in no more than 1 hour of sedentary screen time daily (Willumsen & Bull, 2020). Also, in a recent study, 3- to 4-year-old African American children and children who lived at or below the poverty level were more likely to engage in more than 1 hour of screen time daily compared with other children (Kracht, Webster, & Staiano, 2020). Further, as described shortly, routine physical activity should be a daily occurrence for young children.

For more information about ways to help children lose weight, see the *Connecting Development to Life* interlude.

connecting development to life

Helping Overweight Children Lose Weight

Most parents with an overweight child want to help the child lose weight but aren't aware of the most effective ways to accomplish this goal. Since overweight children are likely to become overweight adolescents and adults, it is important for parents to help their children attain a healthy weight and maintain it. Following are some ways parents can help their overweight children lose weight (DiLeonardo, 2015; Matthiessen, 2015; Moninger, 2015):

- *Work on a healthy project together and involve the child in the decision-making process*. Get the child involved in an activity that helps him or her lose weight, such as installing a pedometer app on family members' smartphones and setting goals for the number of steps or miles walked each day. When children are involved in making decisions about the family's health, they may begin to take responsibility for their own health.
- *Be a healthy model for your child*. In many aspects of life, what people do is more influential than what they say. If parents are overweight and engaging in unhealthy behaviors such as eating unhealthy fast food and being inactive, then simply telling their overweight children to lose weight is unlikely to be effective. In a recent study of Latinx families, parents who had a healthy weight were 3.7 times more likely to have a child who had a healthy weight (Coto & others, 2019).
- *Engage in physical activities with children*. Parents and children can engage in activities like bicycling, jogging, hiking, and swimming together. A parent might say something like "Let's take a bike ride after dinner this evening. It would be fun and could help us both get in better shape."
- *Give children opportunities to decide what they want to do to lose weight*. Take them to the grocery store and let them select the fruits and vegetables they are willing to eat. Let them choose which sport or type of exercise they would like to do.

If their children are overweight, what are some positive strategies parents can adopt to help them lose weight?
Andersen Ross/Blend Images/Getty Images

- *Eat healthy family meals together on a regular basis*. Children who eat meals with their family are less likely to be overweight.
- *Reduce screen time*. Children who spend large numbers of hours per day in screen time are more likely to be overweight than their counterparts who are physically active.

ADOLESCENCE

Nutrition and being overweight are also key problems among adolescents (Telljohann & others, 2020). National data indicated that the percentage of obese U.S. 12- to 19-year-olds increased from 11 percent in the early 1990s to 20.7 percent in 2016 (Hales & others, 2017).

An international study of adolescents in 56 countries found that fast food consumption is high in childhood and continues to increase in adolescence (Braithwaite & others, 2014). In this study, adolescents who ate fast food frequently or very frequently had higher body mass indices than adolescents in the lower frequency categories. A comparison of adolescents in 28 countries found that U.S. adolescents ate more junk food than their counterparts in most other countries (World Health Organization, 2000). The National Youth Risk Survey has found that U.S. high school students show a long-term linear decrease in their intake of fruits and vegetables, with 59.2 percent of high school students not eating vegetables one or more times in the last 7 days in 2019 (Underwood & others, 2020). In recent research, a higher level of parental monitoring was linked to adolescents having a healthier diet and reduced likelihood of being overweight (Kim & others, 2019).

What are some other aspects of adolescents' lives that are linked to being overweight or obese? One study revealed that playing on a sports team was an important factor in adolescents'

weight (Drake & others, 2012). In this study, among a wide range of activities (other physical activity, physical education, screen time, and diet quality, for example), team sports participation was the strongest predictor of lower risk for being overweight or obese. Another study revealed that participating in family meals during adolescence protected against the development of being overweight or obese in adulthood (Berge & others, 2015). Further, increases in screen time in adolescence are associated with adolescent overweight and obesity (Zhu & others, 2019). Also, a recent study of 10- to 17-year-olds found that obesity was linked to poor academic skills (avoidance of academic tasks and a lack of interest in learning, for example) and inadequate coping skills (difficulty staying calm when challenged, for example) (Gill & others, 2021).

What types of interventions have been successful in reducing overweight in adolescents? One review indicated that a combination of calorie restriction, exercise (such as walking or biking to school and participating in a regular exercise program), reduction of sedentary activity (such as watching TV or playing video games), and behavioral therapy (such as keeping weight-loss diaries and receiving rewards for meeting goals) have been moderately effective in helping overweight adolescents lose weight (Fowler-Brown & Kahwati, 2004). Also, a recent meta-analysis concluded that supervised exercise, especially aerobic exercise, was linked to a reduction of abdominal fat in adolescents (Gonzalez-Ruis & others, 2017). And a recent study found that a combination of regular exercise and a diet plan resulted in weight loss and enhanced executive function in adolescents (Xie & others, 2017). Further, an after-school athletics program reduced the obesity risk of adolescents after one year of intervention (Glabska & others, 2019).

Anorexia nervosa has become an increasing problem for adolescent girls and young adult women. *What are some possible causes of anorexia nervosa?*
PeopleImages/E+/Getty Images

Anorexia Nervosa Although most U.S. girls have been on a diet at some point, slightly less than 1 percent ever develop anorexia nervosa. **Anorexia nervosa** is an eating disorder that involves the relentless pursuit of thinness through starvation. It is a serious disorder that can lead to death (Farasat & others, 2020; Yao & others, 2021). According to the *DSM-5* psychiatric classification system, individuals have anorexia nervosa when the following factors are present: (1) restricted energy intake leading to significantly low body weight; (2) presence of intense fear of gaining weight or becoming fat or persistent behavior that interferes with gaining weight; and (3) disturbance in how body weight or shape is experienced or not recognizing the seriousness of the current low weight. Obsessive thinking about weight and compulsive exercise also are linked to anorexia nervosa (Smith, Mason, & Lavender, 2018). Even when they are extremely thin, individuals with this eating disorder see themselves as too fat (Phillipou, Castle, & Rossell, 2019). They never think they are thin enough, especially in the abdomen, buttocks, and thighs. They usually weigh themselves frequently, often take their body measurements, and gaze critically at themselves in mirrors (Askew & others, 2020).

Anorexia nervosa typically begins in the early to middle adolescent years, often following an episode of dieting and some type of life stress (Fitzpatrick, 2012). It is about 10 times more likely to occur in females than males. When anorexia nervosa does occur in males, the symptoms and other characteristics (such as a distorted body image and family conflict) are usually similar to those reported by females who have the disorder (Ariceli & others, 2005).

Although anorexia nervosa can be present in individuals from any ethnic group, it is more common among non-Latinx White adolescent or young adult females who come from well-educated, middle- and upper-income families and are competitive and high-achieving (Darcy, 2012). Individuals with anorexia nervosa often set high standards, become stressed about not being able to reach the standards, and are intensely concerned about how others perceive them (Calugi & Dalle Grave, 2019). Unable to meet these unrealistic expectations, they turn to something they can control—their weight. Also, a recent study revealed that cognitive inflexibility, especially in perfectionistic adolescents, was associated with anorexia nervosa (Buzzichelli & others, 2018). Offspring of mothers with anorexia nervosa are at increased risk for becoming anorexic themselves (Striegel-Moore & Bulik, 2007). Problems in family functioning are increasingly shown to be connected with anorexia nervosa in adolescent girls (Dimitropoulos & others, 2018), and family therapy is often recommended as a treatment for adolescent and emerging adult females with anorexia nervosa (Baumas & others, 2021).

Biology and culture are involved in anorexia nervosa (Kim, Nakai, & Thomas, 2021). Genes play an important role in the development of this disorder (Watson & others, 2021). Also, the physical effects of dieting may change brain functioning and neural networks and thus sustain the disordered pattern (de la Cruz & others, 2021). The thin fashion image in U.S. culture likely contributes to the incidence of anorexia nervosa (Cazzato & others, 2016). The media portray thin as beautiful in their choice of fashion models, whom many adolescent

anorexia nervosa An eating disorder that involves the relentless pursuit of thinness through starvation.

girls strive to emulate (Carr & Peebles, 2012). A recent study found that having an increase in Facebook friends across two years was linked to enhanced motivation to be thin (Tiggemann & Slater, 2017). And many adolescent girls who strive to be thin hang out together.

Bulimia Nervosa

Although anorexics control their eating by restricting it, most bulimics cannot. **Bulimia nervosa** is an eating disorder in which the individual consistently follows a binge-and-purge eating pattern. According to the *DSM-V* classification system, an individual with bulimia nervosa is characterized by: (1) eating in a specific amount of time (such as within a 2-hour time frame) an amount of food that is larger than what most people would eat in a similar period in similar circumstances, and (2) sense of a lack of control of eating during an episode (Gorrell & others, 2019). The bulimic goes on an eating binge and then purges by self-induced vomiting or use of a laxative. Although some people binge and purge occasionally and some experiment with it, a person is considered to have a serious bulimic disorder only if the episodes occur at least twice a week for three months (Castillo & Weiselberg, 2017).

As with anorexics, most bulimics are preoccupied with food, have a strong fear of becoming overweight, and are depressed or anxious (Sattler, Eickmeyer, & Eisenkolb, 2020). Also, a recent meta-analysis concluded that anorexics and bulimics engage in maladaptive perfectionism (Norris, Gleaves, and Hutchinson, 2019). In addition, one study found that bulimics have difficulty controlling their emotions (Lavender & others, 2014). Unlike anorexics, people who binge and purge typically fall within a normal weight range, a characteristic that makes bulimia more difficult to detect.

Bulimia nervosa typically begins in late adolescence or early adulthood. About 90 percent of the cases occur in women. It is estimated that approximately 1 to 2 percent of women develop bulimia nervosa. Many women who develop bulimia nervosa were somewhat overweight before the onset of the disorder, and the binge eating often began during an episode of dieting. Drug therapy and psychotherapy have been effective in treating anorexia nervosa and bulimia nervosa (Hoskins & others, 2019). Cognitive behavior therapy has especially been helpful in treating bulimia nervosa (Hay, 2020).

Binge Eating Disorder (BED)

Binge eating disorder (BED) involves frequent binge eating but without compensatory behavior like the purging that characterizes bulimics (Fauconnier & others, 2020). Individuals with BED engage in recurrent episodes of eating large quantities of food, during which they feel a lack of control of their eating. Because they don't purge, individuals with BED are frequently overweight (Dakanalis & others, 2018). For the first time, binge eating disorder was included by the American Psychiatric Association in the fifth edition of its classification of psychiatric disorders in 2013. As with anorexia nervosa and bulimia disorder, far more females than males develop BED.

Researchers are examining the role of biological and psychological factors in BED (Abdo & others, 2020). Genes play a role, as does dopamine, the neurotransmitter related to reward pathways in the brain (Palmeira & others, 2019). Another study found that adolescents with BED were more likely to live in families with less effective family functioning, especially in the area of emotional involvement (Tetzlaff & others, 2016). Cognitive behavior therapy and pharmacological treatments have been successful with BED patients (Klein, Sylvester, & Schvey, 2021).

ADULT DEVELOPMENT AND AGING

Nutrition and eating behavior continue to play important roles in adult physical development and health. Among the topics we discuss in this section are obesity, exercising and dieting to lose weight, and links between aging, weight, and nutrition.

Obesity

Obesity is a serious and pervasive health problem for many individuals (Insel & Roth, 2022). In the United States, 42.4 percent of adults 20 years and older were classified as obese in 2017–2018 (Hales & others, 2020). This represents a 11.7 percent increase since 2000 and a 7.3 percent increase since 2012. The prevalence of obesity in middle-aged adults (44.8 percent) was higher than in younger adults (40 percent). The prevalence of obesity was similar for men and women, although severe obesity was higher in women (11.5 percent) than men (6.9 percent). In terms of ethnic groups, African Americans (49.6 percent) and Latinxs (44.8 percent) had the highest obesity rates, followed by non-Latinx Whites (42.2 percent). Asian Americans had the lowest rate of obesity by far (17.4 percent). The highest rate of

bulimia nervosa An eating disorder in which the individual consistently follows a binge-and-purge eating pattern.

binge eating disorder (BED) Involves frequent binge eating without compensatory behavior like the purging that characterizes bulimics.

How effective are diet programs?
Cathy Yeulet/Hemera/Getty Images

obesity occurred among African American females (56.9 percent), while the lowest rate was for Asian American females (17.2 percent).

Overweight and obesity are linked to increased risk of earlier death, hypertension, diabetes, and cardiovascular disease (Schiff, 2022). For individuals who are 30 percent overweight, the probability of dying in middle adulthood increases by about 40 percent. Also, in a recent large-scale study, obesity was associated with shorter longevity and increased risk of death due to cardiovascular disease compared with normal-weight individuals (Khan & others, 2018).

Overweight and obesity also are associated with mental health problems (Majd & others, 2021). For example, in a research review, depression was linked to abdominal obesity in older adults (Repousi & others, 2018). Also, in a recent study, women—especially those who were overweight—reported increased anxiety, depression, and loneliness during the COVID-19 pandemic (Lofrano-Prado & others, 2021).

What causes obesity? Some individuals do inherit a tendency to be overweight (Masip & others, 2020). Only 10 percent of children who do not have obese parents become obese themselves, whereas 40 percent of children who become obese have one obese parent. Further, 70 percent of children who become obese have two obese parents. Researchers also have documented that animals can be inbred to have a propensity for obesity (Derman & Ferrario, 2018).

Environmental factors play an important role in obesity (Donatelle & Ketcham, 2020). Strong evidence of the environment's influence on weight is the doubling of the rate of obesity in the United States since 1900. This dramatic increase in obesity likely is due to greater availability of food (especially food high in fat), labor-saving devices, and declining physical activity.

Sociocultural factors are involved in obesity, which is six times more prevalent among women with low incomes than among women with high incomes. Americans also have higher rates of obesity than Europeans and people in many other areas of the world. For example, in recent international comparisons of 33 countries, the average obesity rate was 23.2 percent. The United States had the highest adult obesity rate (38.2 percent), followed by Mexico (32.4 percent), and Japan had the lowest rate (3.7 percent), followed by South Korea (5.3 percent) (OECD, 2017).

Losing Weight One fact that we *do* know about losing weight is that the most effective programs include exercise (Hynes, 2020). Researchers have found that higher levels of physical activity, especially endurance training, are linked to weight loss maintenance (Secor, 2020). Although many Americans regularly embark on a diet, few are successful in keeping weight off over the long term and many dieters risk becoming fatter (Corbin & others, 2019). However, some individuals do lose weight and maintain the loss (Szabo-Reed & others, 2020). A research review concluded that adults who engaged in diet-plus-exercise programs lost more weight than those who relied on diet-only programs (Wu & others, 2009). And a study of approximately 2,000 U.S. adults found that exercising 30 minutes a day, planning meals, and weighing themselves daily were the main strategies used by successful dieters compared with unsuccessful dieters (Kruger, Blanck, & Gillespie, 2006) (see Figure 9).

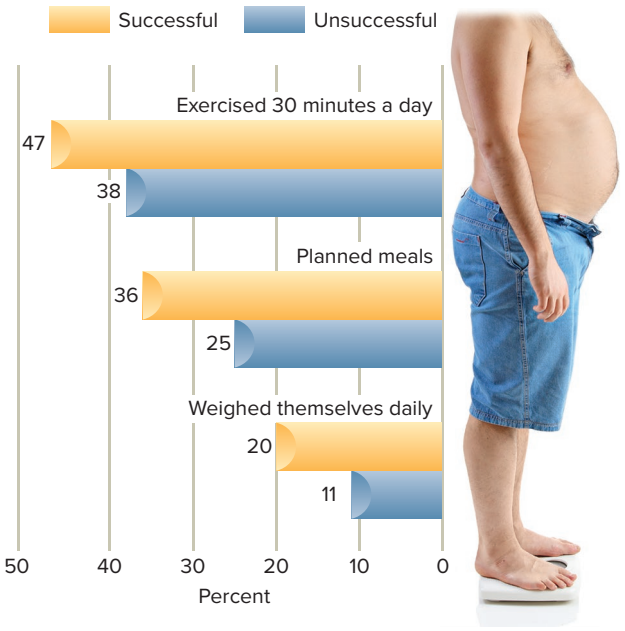

FIGURE **9**
COMPARISON OF STRATEGIES USED BY SUCCESSFUL AND UNSUCCESSFUL DIETERS.
Ljupco Smokovski/Essentials/Getty Images

Nutrition and Aging Eating a healthy, balanced diet and taking appropriate vitamins can help older adults maintain their health (Schiff, 2022).

Overweight and Obesity A national survey found that 42.8 percent of U.S. adults 60 years of age and older were obese in 2017–2018 (Centers for Disease Control and Prevention, 2021). This figure is lower than the 44.8 percent of individuals 40 to 59 years of age who were obese. In this survey, 42.2 percent of men and 43.3 percent of women 60 years of age and older were obese.

Despite several studies that have found a link between being overweight and living longer, the majority of studies have revealed that being overweight is a risk factor for an earlier death (Zhang & others, 2019). For example, in a recent large-scale study, obesity was associated with shorter longevity and increased risk of death due to cardiovascular disease compared with normal-weight individuals (Khan & others, 2018).

However, although the link between obesity and disease is present in older adults, the link is weaker than it is for young and middle-aged adults (Kalish, 2016). Researchers also consistently find that when individuals are

overweight and fit, they have a much better health profile and greater longevity than those who are overweight and not fit (Sardinha & others, 2016).

Calorie Restriction and Longevity Some studies have shown that calorie restriction in laboratory animals (such as rats and roundworms) can increase the animals' longevity (Yamada & others, 2020). And researchers have found that chronic problems such as cardiovascular, kidney, and liver disease appear at a later age when calories are restricted (Hegab & others, 2019). In addition, some recent research indicates that calorie restriction may provide neuroprotection for aging central nervous and immune systems (Yamada & others, 2020). Also, in a recent research review, calorie restriction reduced inflammation in normal brain aging as well as neurodegenerative diseases such as Alzheimer disease (Fontana & others, 2021).

No one knows for certain how calorie restriction (CR) works to increase the life span of animals. Some scientists suggest that CR might lower the level of free radicals and reduce oxidative stress in cells (Gultekin & others, 2018). Others argue that CR might trigger a state of emergency called "survival mode" in which the body eliminates all unnecessary functions to focus on staying alive (Moatt & others, 2019).

Whether very low-calorie diets can stretch the human life span is not known. In some instances, the animals in these studies consumed 40 percent fewer calories than normal. In humans, a typical level of calorie restriction involves a 30 percent decrease, resulting in about 1,120 calories a day for the average woman and 1,540 for the average man. In conclusion, the research findings on the effects of calorie restriction in humans are mixed (Locher & others, 2016). Thus, an appropriate conclusion at this time is that further research is needed to definitively determine whether calorie restriction increases longevity, especially in humans (Kirkham, Beka, & Prado, 2021).

The Controversy Over Vitamins and Aging For years, most experts on aging and health argued that a balanced diet was all that was needed for successful aging; vitamin supplements were not recommended. However, researchers recently began exploring the possibility that some vitamin supplements—mainly a group called "antioxidants" consisting of vitamin C, vitamin E, and beta-carotene—might help to slow the aging process and improve the health of older adults (Tabibzadeh, 2021).

The theory is that antioxidants counteract the cell damage caused by free radicals, which are produced both by the body's own metabolism and by environmental factors such as smoking, pollution, and harmful chemicals in the diet (Milisav, Ribaric, & Poljsak, 2018). When free radicals cause damage (oxidation) in one cell, a chain reaction of damage follows. In this theory, antioxidants act much like a fire extinguisher, helping to neutralize free-radical activity.

What have research studies found about the role of antioxidants in health? In two studies, no link was found between antioxidant vitamin intake and mortality (Henriquez-Sanchez & others, 2016; Stepaniak & others, 2016). Additionally, research reviews have not supported the belief that antioxidant vitamin supplements can reduce the incidence of cancer and cardiovascular disease (Khodaeian & others, 2015; Paganini-Hill, Kawas, & Corrada, 2015). Also, in a recent analysis, it was concluded that antioxidant supplements do not increase the life span and even can increase the incidence of diseases (Millsav, Ribaric, & Poljsak, 2018).

3 Exercise

LG3 Summarize the roles of exercise in child and adult health.

Childhood and Adolescence | Adulthood | Aging and Longevity

We have seen the important role exercise plays in losing weight. Exercise is linked with many aspects of physical and mental health. Let's explore the impact of exercise throughout the life span.

CHILDHOOD AND ADOLESCENCE

American children and adolescents are not getting enough exercise (Rink, 2020; Wuest & Walton-Fisette, 2021). Educators and policy makers in the United States and numerous countries around the world, including China, Finland, and Great Britain, have become very concerned about the sedentary lifestyles of many children and adolescents in their countries (Dumuid & others, 2017; Ndabi, Nevill, & Sandercock, 2019; Shao, Wang, & Chen, 2020; Tomkinson & Wong, 2019).

Childhood U.S. children are not getting enough exercise (Lumpkin, 2021). Children should engage in physical activity every day (Rink, 2020). The World Health Organization (2019) recently recommended that 3- to 4-year-olds spend at least 3 hours per day engaging in a variety of physical activities of any intensity, of which at least 60 minutes should consist of moderate- to vigorous-intensity physical activity, spread throughout the day. These guidelines reflect an increase from earlier guidelines (National Association for Sport and Physical Education, 2002). The child's life should center around activities, not meals.

Also, a recent study examined children's physical activity as they made the transition from elementary to middle school (Pate & others, 2019). In this study, the following activities were associated with children's greater physical activity: parents' encouragement of physical activity, parents' support of physical activity, time children spent outdoors, children's sports participation, and number of physical activity facilities near their home.

An increasing number of studies document the importance of exercise in children's physical development (Meeks, Heit, & Page, 2020). A study of more than 6,000 elementary school children revealed that 55 minutes or more of moderate-to-vigorous physical activity daily was associated with a lower incidence of obesity (Nemet, 2016). In addition, a recent study indicated that regular physical activity combined with a high level of calcium intake increased the bone health of 3- to 18-year-olds (Yang & others, 2020). Also, a study of 7- to 9-year-olds found that participating in organized leisure-time sports for approximately one year was linked to reduced

How much physical activity should preschool children engage in per day?

cardiovascular risk (Hebert & others, 2017). And a recent research review of 27 studies concluded that aerobic exercise was associated with children's reduction of body fat, lower fasting insulin levels, decreased inflammatory markers, and increased physical fitness (Lee, 2021).

Children's brain and cognitive development also benefit from regular exercise. Researchers have found that aerobic exercise improves children's attention, memory, effortful and goal-directed thinking and behavior, creativity, academic success, and literacy (Sun & others, 2021). For example, in a study of physically unfit 8- to 11-year-old overweight children, a daily instructor-led aerobic exercise program that lasted eight months was effective in improving the efficiency or flexible modulation of neural circuits that support better cognitive functioning (Kraftt & others, 2014). In addition, a recent meta-analysis concluded that sustained physical activity programs were linked to improvements in children's attention, executive function, and academic achievement (de Greeff & others, 2018). Another recent meta-analysis concluded that prolonged exercise interventions with 6- to 12-year-olds that consisted of multiple exercise activities per week and lasted for more than 6 weeks were effective in improving the children's executive function in general and their inhibitory control in particular (Xue, Yang, & Huang, 2019). Also, a recent research review concluded that physical activity interventions improved the cognitive performance (especially executive function) of overweight or obese children (Sun & others, 2021).

Parents and schools strongly influence children's exercise habits (Sun & others, 2021). Growing up with parents who exercise regularly provides positive models of exercise for children. Also, a study found that school-based physical activity was successful in improving children's fitness and lowering their levels of body fat (Kriemler & others, 2011).

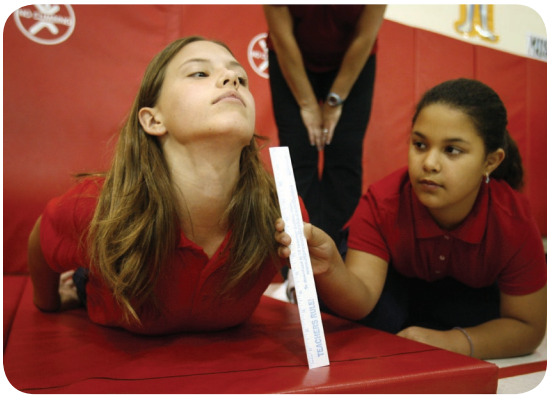
Adolescence Researchers have found that individuals tend to become less active as they reach and progress through adolescence (Chong & others, 2020). Also, a recent national survey found that in 2019, 23 percent of ninth- to twelfth-graders had engaged in physical activity for 60 minutes or more in each of the last seven days, compared with 28.7 percent in 2011 (Underwood & others, 2020). Adolescent girls were much less likely to have engaged in physical activity for 60 minutes or more per day in each of the last seven days (15.4 percent) than were boys (30.9 percent) (Underwood & others, 2020).

Ethnic differences in exercise participation rates of U.S. adolescents also occur, and these rates vary by gender. In the National Youth Risk Survey, non-Latinx White boys exercised the most and African American girls the least (Underwood & others, 2020).

Exercise is linked to a number of positive physical outcomes in adolescence (Lumpkin, 2021). For example, regular exercise has a positive effect on adolescents' weight status (Saidi & others, 2020). Other positive physical outcomes of exercise in adolescence are reduced triglyceride levels, lower blood pressure, and a lower incidence of type 2 diabetes (Huang & others, 2020). One study found that adolescents who were high in physical fitness had better connectivity between brain regions than adolescents who were low in physical fitness (Herting & others, 2014). Also, in another study, an exercise program of 180 minutes per week improved the sleep patterns of obese adolescents (Mendelson & others, 2016). And a recent experimental study of obese adolescent girls found that a 12-week jump rope exercise program was effective in improving their body composition, blood pressure, insulin level, and self-regulation (Kim & others, 2020).

Exercise in adolescence also is linked to other positive outcomes, including academic, cognitive, and socioemotional development (Kemp & others, 2020). In a recent study, adolescents who exercised regularly had higher academic achievement than those who did not (Owen & others, 2018). In terms of socioemotional development, a recent large-scale study of Dutch adolescents found that those who were physically active has fewer emotional and peer problems (Kuiper, Broer, & van der Wouden, 2018). Further, a recent study of adolescents with major depressive disorder (MDD) revealed that engaging in aerobic exercise for 12 weeks reduced their depressive symptoms (Jaworska & others, 2019). And in a recent Chinese study, adolescents showed more depressive symptoms after COVID-19 appeared; however, engaging in more physical exercise during the quarantine helped to buffer the link between the pandemic and depressive symptoms (Ren & others, 2021).

As with children, parents play an important role in influencing adolescents' exercise patterns (Baker & others, 2020). Also, a research review found that peers' support of exercise has an especially strong influence on adolescents' physical



In 2007, Texas became the first state to test students' physical fitness. The student shown here is performing the trunk lift. Other assessments include aerobic exercise, muscle strength, and body fat. Assessments are done annually.

THE JOGGING HOG EXPERIMENT. Jogging hogs reveal the dramatic effects of exercise on health. In one investigation, a group of hogs was trained to run approximately 100 miles per week (Bloor & White, 1983). Then the researchers narrowed the arteries that supplied blood to the hogs' hearts. The hearts of the jogging hogs developed extensive alternate pathways for blood supply, and 42 percent of the threatened heart tissue was salvaged compared with only 17 percent in a control group of nonjogging hogs.

PHYSICAL FITNESS AND MORTALITY. In a study of middle-aged and older adults, being moderately fit or highly fit meant that individuals were less likely to die over a period of eight years than their less fit (sedentary) counterparts (Blair & others, 1989).

aerobic exercise Sustained activity that stimulates heart and lung functioning.

activity (Fitzgerald, Fitzgerald, & Aherne, 2012). Schools also can influence adolescents' exercise levels and developmental outcomes. In a recent study, a school-based exercise program of 20 minutes of exercise a day over 8 weeks improved students' working memory (Ludyga & others, 2018).

ADULTHOOD

The benefits of exercise continue in adulthood. Both moderate and intense exercise produce important physical and psychological gains (Fahey, Insel, & Roth, 2021). The enjoyment and pleasure we derive from exercise added to its physical benefits make exercise one of life's most important activities (Lumpkin, 2021). The World Health Organization recognizes physical inactivity as a key factor in dying earlier (Han, Neufer, & Pilegaard, 2019). A recent national U.S. poll conducted by the Centers for Disease Control and Prevention found that only 22.9 percent of U.S. adults 18 to 64 years of age met federal guidelines for aerobic and muscle-strengthening exercise (Blackwell & Clarke, 2018). In this poll, 27.2 percent of men and 18.7 percent of women met the exercise guidelines.

Among the most important health benefits of exercise are reduced risks for obesity, cardiovascular disease, and diabetes (Insel & Roth, 2022). Even getting hogs to jog has documented the cardiovascular benefits of exercise (see Figure 10).

Researchers have found that exercise benefits not only the physical health of adults but their mental health as well (Orstad & others, 2020). For example, in a recent study of almost 18,000 adults, engaging in both regular moderate-to-vigorous physical activity and muscle-strengthening exercise was associated with the lowest incidence of depressive symptoms (Bennie & others, 2019). And a one-year exercise intervention was linked to decreased stress symptoms in working adults (Kettunen, Vuorimaa, & Vasankari, 2015).

Although exercise designed to strengthen muscles and bones or to improve flexibility is important to fitness, many health experts stress the benefits of aerobic exercise. **Aerobic exercise** is sustained activity—jogging, swimming, or cycling, for example—that stimulates heart and lung functioning.

Many health experts recommend that adults engage in 45 minutes or more of moderate physical activity on most, or preferably all, days of the week. Most recommend trying to raise your heart rate to at least 60 percent of your maximum heart rate. However, only about one-fifth of adults achieve these recommended levels of physical activity.

AGING AND LONGEVITY

Although we may be in the evening of our lives in late adulthood, we are not meant to live out our remaining years passively. Everything we know about older adults suggests that their health and happiness are linked with how active they are (Di Lorito & others, 2021; Peven, Stillman, & Erickson, 2020). Can regular exercise lead to a healthier, more satisfying late adulthood and increased longevity? Let's examine several research studies on exercise and aging.

A recent study confirmed that older adults who engage in regular exercise have a higher level of life satisfaction (Cho & Kim, 2020). In another study, exercise literally meant a difference between life and death for middle-aged and older adults (Blair, 1990). More than 10,000 men and women were divided into categories of low fitness, medium fitness, and high fitness (Blair & others, 1989). Then they were studied over a period of eight years. As shown in Figure 11, sedentary participants (low fitness) were more than twice as likely to die during the eight-year time span of the study as those who were moderately fit and more than three times as likely to die as those who were highly fit. The positive effects of being physically fit occurred for both men and women in this study. Also, a longitudinal study found that men who exercised regularly at 72 years of age had a 30 percent higher probability of still being alive at 90 years of age than their sedentary counterparts (Yates & others, 2008).

Gerontologists increasingly recommend strength training in addition to aerobic activity and stretching for older adults (Kneffel & others, 2021; Naczk, Marszalek, & Naczk, 2020). The average person's lean body mass declines with age—about 6.6 pounds of lean muscle are lost each decade during the adult years. The rate of muscle loss accelerates after age 45. Resistance exercise can preserve and possibly increase muscle mass in older adults (Miller,

Bemben, & Bemben, 2021). A recent meta-analysis concluded that elastic band resistance training improved older adults' lower body function and muscle quality (Herda & Nabavizadeh, 2021). Exercise is an excellent way to maintain health and live longer (Fahey, Insel, & Roth, 2021). The current recommended level of aerobic activity for adults 60 years of age and older is 30 minutes of moderately intense activity, such as brisk walking or riding a stationary bicycle, five or more days a week, and strength training two or more days a week (Centers for Disease Control and Prevention, 2020a).

Researchers continue to document the positive effects of exercise in older adults:

- *Exercise is linked to increased longevity*. A recent meta-analysis confirmed that physically active older adults have an increased likelihood of living longer (Cunningham & others, 2020). Also, a recent study of middle-aged adults revealed that their estimated age based on exercise stress testing was a better predictor of how long they would live than their chronological age (Harb & others, 2020).
- *Exercise is related to prevention of common chronic diseases*. Exercise can reduce the risk of developing arthritis, cardiovascular disease, type 2 diabetes, osteoporosis, stroke, and breast cancer (Silveira-Rodrigues & others, 2021).
- *Exercise is associated with improved outcomes for many diseases*. When exercise is used as part of the treatment, individuals with the following disorders show improvement in symptoms: arthritis, pulmonary disease, congestive heart failure, coronary artery disease, hypertension, type 2 diabetes, obesity, and Alzheimer disease (Finn & others, 2021; Nelson & others, 2020).
- *Exercise improves older adults' cellular functioning*. Researchers increasingly are finding that exercise improves cellular functioning in older adults. For example, a recent research review concluded that exercise is the most effective behavioral intervention for improving mitochondrial health (Memme & others, 2021).
- *Exercise improves immune system functioning in older adults.*
- *Exercise can optimize body composition and reduce the decline in motor skills as aging occurs*. Exercise can increase muscle and bone mass, improve balance and reduce falls, as well as decrease bone fragility (Sibley & others, 2021).
- *Exercise reduces the likelihood that older adults will develop mental health problems and can be effective as part of the treatment of mental health problems* (Brady & others, 2021). For example, a recent meta-analysis concluded that moderate to vigorous physical exercise was effective in reducing depressive symptoms in older adults with a mean age of 82 years (Klil-Drori & others, 2020).
- *Exercise is linked to improved brain and cognitive functioning in older adults*. Older adults who exercise show better brain functioning and more efficient processing of information than older adults who don't exercise (Hegberg, Dev, & Hayes, 2020). A recent research review concluded that greater physical activity in community-dwelling older adults is associated with larger brain volume (less brain atrophy) in the hippocampal, temporal lobe, and frontal lobe regions (Domingos, Pego, & Santos, 2021). Also, in a recent meta-analysis, regular physical exercise training, especially aerobic exercise, improved working memory, executive function, and cognitive flexibility in cognitively healthy older adults (Xiong & others, 2021).

Johnny Kelley finishes one of the many Boston Marathons he ran as an older adult. In 1991, he ran his sixteenth Boston Marathon, and in 2000, he was named "Runner of the Century" by *Runner's World* magazine. At 70 years of age, Kelley was still running 50 miles a week. At that point in his life, Kelley said, "I'm afraid to stop running. I feel so good. I want to stay alive." He lived 27 more years and died at age 97 in 2004.
Charles Krupa/AP Images

Despite the extensive research documenting the power of exercise to improve older adults' health and quality of life, many older adults do not engage in any exercise. In the United States, physical inactivity increases with age. By age 75, about one in three men and one in two women engage in no physical exercise (Centers for Disease Control and Prevention, 2020a).

Possible explanations of older adults' reduction in exercise compared with middle-aged adults focus on such factors as chronic illnesses, life crises (such as a spouse's death) that disrupt exercise schedules, embarrassment at being around others who are in better shape (especially if they haven't exercised much earlier in life), and the "why bother?" factor (not believing that exercise will improve their lives much). But as we have seen, it is never too late to begin exercising, and older adults can significantly benefit from regular exercise (Peven, Stillman, & Erickson, 2020). A recent study even found that when older adults regularly walk their dog it predicts better health for them (Curl, Bibbo, & Johnson, 2017).

4 Substance Use

LG4 Evaluate substance use in adolescence and adulthood.

Adolescence and Emerging Adulthood

Substance Use in Older Adults

In addition to exercising, another important way to preserve health is not to engage in substance abuse (Hart & Ksir, 2022). In one longitudinal study, individuals who did not abuse alcohol at age 50 were more likely to still be alive and healthy at 75 to 80 years of age than their counterparts who abused alcohol at age 50 (Vaillant, 2002). In the chapter titled "Biological Beginnings," we described the negative effects on the fetus and developing child that can result from substance use by the pregnant mother. Here we examine the effects of substance use on adolescents, emerging adults, and older adults.

ADOLESCENCE AND EMERGING ADULTHOOD

Adolescence is a critical time for the onset of substance abuse (Maisto, Galizio, & Connors, 2022). Many individuals who abuse drugs begin doing so as adolescents. Let's explore some trends in adolescent drug use and then examine drug use in emerging adulthood.

Trends in Adolescent Drug Use Each year since 1975, researchers at the Institute of Social Research at the University of Michigan have monitored the drug use of America's high school seniors in a wide range of public and private high schools. Since 1991, they also have surveyed drug use by eighth- and tenth-graders. In 2019, the study surveyed more than 42,531 secondary school students in 397 public and private schools (Miech & others, 2020).

According to the study, drug use among U.S. secondary school students declined in the 1980s but began to increase in the early 1990s (Johnston & others, 2021). The proportions of eighth-, tenth-, and twelfth-grade U.S. students who used any illicit drug declined in the late 1990s and the first two decades of the twenty-first century (Miech & others, 2020). The most notable declines in drug use by U.S. adolescents in the twenty-first century have occurred for LSD, cocaine, cigarettes, sedatives, tranquilizers, and Ecstasy. Marijuana is the illicit drug most widely used in the United States and Europe (Hibell & others, 2004; Miech & others, 2020). In the second decade of the twenty-first century, a leveling off of illicit drug use overall by adolescents has been occurring, which continued in 2020 (Johnston & others, 2021). Even with the recent decline and leveling off in use, however, the United States still has one of the highest rates of adolescent drug use of any industrialized nation.

Regarding the slight decline and leveling off of any illicit drug use recently, in the past month, for twelfth-graders it was at 22.2 percent compared with 23.7 percent in 2010; for tenth-graders it was 18.2 percent in 2020 compared with 18.5 percent in 2010; and for eighth-graders it was 8.7 percent in 2020 compared with 9.5 percent in 2010 (Johnston & others, 2021). If marijuana is subtracted from total illicit drug use, a significant decrease has occurred: twelfth-grade use of drugs in 2020 was 4.8 percent compared with 8.6 percent in 2010, for example.

How extensive is alcohol use among U.S. adolescents? Sizable declines in adolescent alcohol use have occurred in recent years (Johnston & others, 2021). The percentage of U.S. twelfth-graders who reported having had any alcohol to drink in the past 30 days fell from 41.2 percent in 2010 to 33.6 percent in 2020. The 30-day prevalence fell among tenth-graders from 28.9 percent in 2010 to 20.3 percent in 2020 and among eighth-graders from 13.8 percent in 2010 to 9.9 percent in 2020. Binge drinking (defined in the University of Michigan surveys as having five or more drinks in a row in the last two weeks) by high school seniors declined from 26.8 percent in 2010 to 19.8 percent in 2020. Binge drinking by eighth- and tenth-graders also has dropped considerably in recent years. A consistent gender difference occurs in binge drinking, with males engaging in this behavior more than females do (Johnston & others, 2021).

A special concern is adolescents who drive while they are under the influence of alcohol or other substances. In a recent study, twelfth-grade binge drinking was linked to driving while impaired (DWI), riding with an impaired driver (RWI), blackouts, and riskier driving up to 4 years later (Vaca & others, 2020). There is an increasing concern about adolescents who mix alcohol and energy drinks, which is linked to a higher rate of risky driving (Wilson & others, 2018).

Cigarette smoking is decreasing among adolescents. Cigarette smoking among U.S. adolescents peaked in 1996 and 1997 and has gradually declined overall since then (Johnston & others, 2021). Following peak use in 1996, smoking rates for U.S. eighth-graders have fallen by 50 percent. In 2020, the percentages who said they had smoked cigarettes in the last 30 days were 7.5 percent for twelfth-graders (an 11 percent decrease from 2011), 3.2 percent for tenth-graders, and 2.2 percent for eighth-graders.

Among U.S. adolescents, rates of e-cigarette smoking have now far surpassed rates of regular cigarette smoking. In 2018, 20.9 percent of twelfth-graders, 16.1 percent of tenth-graders, and 6.1 percent of eighth-graders reported vaping nicotine (Johnston & others, 2021). And in 2020, further increases in vaping nicotine occurred—in the last 30 days, the figures were 24.7 percent of twelfth-graders, 19.3 percent of tenth-graders, and 10.5 percent of eighth-graders. Recent research suggests a gateway effect of e-cigarette use not only for future combustible cigarette smoking but marijuana use as well (Fadus, Smith, & Squeglia, 2019).

Marijuana, a milder hallucinogen than LSD, comes from the hemp plant *Cannabis sativa*. Because marijuana also can impair attention and memory, smoking marijuana is not conducive to optimal school performance. Marijuana use by adolescents decreased in the 1980s. For example, in 1979, 37 percent of high school seniors said they had used marijuana in the last month, but in 1992 that figure had dropped to 19 percent and in 2006 to 18 percent. However, marijuana use by U.S. adolescents has increased in recent years. For example, in 2020, 21.1 percent of U.S. twelfth-graders reported that they had smoked marijuana in the last 30 days (Johnston & others, 2021). Reasons that marijuana use has recently increased are the trend that fewer adolescents today perceive much danger associated with its use and greater ease of access to marijuana, especially because of greater availability in the increasing number of states where marijuana use is legal for adults.

The Roles of Development, Parents, Peers, and Educational Success A special concern involves adolescents who begin using drugs early in adolescence or even in childhood (Hart & Ksir, 2022). A longitudinal study of individuals from 8 to 42 years of age also found that early onset of drinking was linked to increased risk of heavy drinking in middle age (Pitkanen, Lyyra, & Pulkkinen, 2005). Another study revealed that the onset of alcohol use before age 11 was linked to a higher risk of alcohol dependence in early adulthood (Guttmannova & others, 2012).

Parents play an important role in preventing adolescent drug abuse (Meisel & Colder, 2021; Voce & Anderson, 2020). In one study, parental knowledge of the adolescent's activities and whereabouts at age 13 was linked to lower alcohol use at age 16 for girls and boys

developmental **connection**
Biological Processes
Early maturation in adolescence is linked with an increased likelihood of substance abuse problems in adolescent girls. Connect to "Physical Development and Biological Aging."

(Lindfors & others, 2019). Also, in a meta-analysis of parenting factors involved in adolescent alcohol use, higher levels of parental monitoring, support, and involvement were associated with a lower risk of adolescent alcohol misuse (Yap & others, 2017). In addition, a research review concluded that the more frequently adolescents ate dinner with their family, the less likely they were to have substance abuse problems (Sen, 2010). Finally, a recent study of 14- to 15-year-olds revealed that heavy episodic drinking by parents was a risk factor for adolescent drinking, with girls being especially vulnerable to the influence of their parents' heavy episodic drinking (Homel & Warren, 2019).

Peer relations also are linked to adolescent substance use. If adolescents' peers and friends use drugs, the adolescents are more likely to also use drugs (Herold & others, 2021). For example, in a recent study, both parent-adolescent relationships and deviant peer affiliations were linked to adolescent substance use, but deviant peer affiliations had a stronger effect on adolescents' use of multiple drugs (Greenwood & others, 2021). Also, a large-scale national study of adolescents indicated that friends' use of alcohol was a stronger influence on alcohol use than parental use (Deutsch, Wood, & Slutske, 2018). And a recent study of 15- to 25-year-olds revealed that online peer group affiliation and belonging were linked to stimulant and opioid use (Miller & others, 2021).

Educational success is a strong buffer against the emergence of drug problems in adolescence (Kendler & others, 2018). An analysis by Jerald Bachman and his colleagues (2008) revealed that early educational achievement considerably reduced the likelihood that adolescents would engage in alcohol abuse, smoking, and abuse of various illicit drugs.

Emerging Adults' Drug Use The transition from high school to college is often a critical risk period for alcohol abuse (Haardorfer & others, 2021; Prince, Read, & Colder, 2019). The large majority of emerging adults recognize that drinking is common among individuals their age and is largely acceptable or even expected by their peers. They also perceive that they get some social and coping benefits from alcohol use and even occasional heavy drinking. One study revealed that only 20 percent of college students reported that they abstain from drinking alcohol (Huang & others, 2009).

In surveys of drinking, binge drinking is usually defined as having 5 or more drinks in a row in the 2 weeks prior to the survey. Recent data from the *Monitoring the Future* study at the University of Michigan indicate that binge drinking peaked at 21 to 22 years of age and then declined through the remainder of the twenties (Schulenberg & others, 2019). While drinking rates among college students have remained high, rates of drinking, including binge drinking, have declined in recent years. For example, binge drinking declined from 37 percent in 2012 to 28 percent in 2018 (Schulenberg & others, 2019).

Heavy drinking takes a toll on college students (Creswell & others, 2020). In a national survey of drinking patterns on 140 campuses, almost half of the binge drinkers reported problems that included missed classes, physical injuries, trouble with police, and unprotected sex (Wechsler & others, 2002). This survey also found that binge-drinking college students were eleven times more likely to drive after drinking and twice as likely to have unprotected sex as college students who did not binge drink. And a longitudinal study revealed that frequent binge drinking and marijuana use during the freshman year of college predicted delayed college graduation (White & others, 2018).

What kinds of problems are associated with binge drinking in college?
Sean Murphy/Photodisc/Getty Images

Drinking alcohol before going out—called *pregaming*—has become common among college students, not just in the United States but other countries as well (Pedersen & others, 2020; Zamboanga & others, 2021). One study revealed that almost two-thirds of students on one campus had pregamed at least once in a two-week period (DeJong, DeRicco, & Schneider, 2010). Drinking games, in which the goal is to become intoxicated, also have become common on college campuses. Higher levels of alcohol use have been consistently linked to higher rates of sexual risk taking, such as engaging in casual sex without using contraceptives, as well as increased risk of being a perpetrator or victim of sexual assault (Looby & others, 2019).

Do individuals smoke cigarettes more in emerging adulthood than in adolescence? Smoking half a pack of cigarettes daily occurs more often among individuals in their twenties than among high school seniors, as many light and moderate smokers in high school transition into a pattern of heavier use after high school (Johnston & others, 2019). Overall, though, cigarette

smoking has been declining significantly among all age groups. However, recently, just as there has been in adolescence, there has been a dramatic increase in use of e-cigarettes among individuals in emerging and early adulthood (Schulenberg & others, 2019). And there has been a significant increase in marijuana use by college students. In 2011, 33 percent of college students reported using marijuana, but that percentage had increased to 43 percent by 2018 (Schulenberg & others, 2019).

SUBSTANCE USE IN OLDER ADULTS

As indicated earlier, use of alcohol and illicit substances peaks in emerging adulthood and then declines somewhat by the mid-twenties. Of course, alcohol and substance abuse continue to raise serious health concerns for many people in early and middle adulthood. How extensive is substance abuse among older adults? A national survey found that in 2010 the percentage of individuals who engaged in binge drinking (defined as four or more drinks for women and five or more drinks for men on one occasion in the past 30 days) declined considerably in middle and late adulthood compared with early adulthood (Centers for Disease Control and Prevention, 2012) (see Figure 12). However, the frequency of binge drinking in the past 30 days was highest in older adults (5.5 episodes).

Age Group	Percent	Drinks Per Occasion	Frequency
18–24	28	9	4.2
25–34	28	8	4.2
35–44	19	8	4.1
45–64	13	7	4.7
65 & over	4	5	5.5

FIGURE **12**

BINGE DRINKING THROUGH THE LIFE SPAN. *Note*: Percent refers to percent of individuals in a particular age group who engaged in binge drinking on at least one occasion in the past 30 days (4 or more drinks for women, 5 or more for men). Drinks per occasion reflects the intensity of the binge drinking. Frequency indicates the number of occasions in which binge drinking occurred in the past 30 days.

Although there has been a decline in binge drinking in late adulthood, the Substance Abuse and Mental Health Services Administration (2005) has identified substance abuse among older adults as an "invisible epidemic" in the United States. The belief is that substance abuse often goes undetected in older adults, and there is concern about older adults who abuse not only illicit drugs but prescription drugs as well (Caplau & others, 2020). Optimization of drug use, especially not overdosing, is a key factor in successful aging (Petrovic & others, 2019). The consequences of abuse—such as depression, inadequate nutrition, congestive heart failure, and frequent falls—may erroneously be attributed to other medical or psychological conditions (Hoyer & Roodin, 2009). As the number of older adults rises, substance abuse is likely to characterize an increasing number of older adults. For older adults who are taking multiple medications, the dangers of substance abuse rise. For example, when combined with tranquilizers or sedatives, alcohol use can impair breathing, produce excessive sedation, and even be fatal.

Despite the concerns about substance abuse in later adulthood, researchers have found a protective effect of moderate alcohol use in older adults (O'Keefe & others, 2014). One study of older adults revealed that those who drank moderately (compared with those who drank heavily or did not drink at all) had better physical and mental health as well as increased longevity (Rozzini, Ranhoff, & Trabucchi, 2007). And a recent study revealed that moderate drinkers were more likely to be alive and not have a cognitive impairment at 85 years of age (Richard & others, 2017). The explanation of moderate drinking's benefits involves better physical and mental performance, being more open to social contacts, and being able to assert mastery over one's life.

Researchers have especially found that moderate drinking of red wine is linked to better health and increased longevity (Li & others, 2019). Explanations of the benefits of red wine involve its connection to lowering stress and reducing the risk of coronary heart disease (Farkhondeh & others, 2020). Evidence is increasing that a chemical in the skin of red wine grapes—resveratrol—plays a key role in red wine's health benefits (Cheng & others, 2020). A recent meta-analysis found that resveratrol was linked to improvement in systolic blood pressure (Weaver & others, 2021). In other research, resveratrol has been found to reduce pulmonary arterial hypertension (Mirhadi & others, 2021). Further, in recent research, resveratrol's anti-cancer effects included suppression of tumor growth (Brockmueller & others, 2021). In addition, scientists are exploring how resveratrol might activate SIRT1, an enzyme that is involved in DNA repair and aging (Caldeira & others, 2021; Wu & others, 2020).

What might explain the finding that drinking red wine in moderation is linked to better health and increased longevity?

Health

1 Health, Illness, and Disease

LG1 Describe developmental changes in health.

Children's Health

- Prevention and poverty are important factors in children's health. Children need timely immunizations. Accident prevention is a key aspect of children's health. Of special concern are children living in poverty, who often are malnourished. A major concern is the number of children in the world who die before reaching 5 years of age and the poor health conditions for children in many countries.

Adolescents' Health

- Adolescence is a critical juncture in health because many health habits—good or bad—are being formed during this period. Social contexts, including family, peers, and schools, influence the health of adolescents.

Emerging and Young Adults' Health

- Few emerging and young adults have chronic health problems. However, many emerging and young adults don't stop to think about how their personal lifestyles will affect their health later in life. Emerging adults have double the mortality rate of adolescents.

Health and Aging

- Chronic disorders increase in middle-aged adults and are common in older adults. Osteoporosis is a concern, especially among older women. Various forms of dementia, especially Alzheimer disease, are a major health problem. Another type of brain disorder is Parkinson disease. A special concern is the quality of nursing homes for older adults and the treatment of older adults in nursing homes.

2 Nutrition and Eating Behavior

LG2 Characterize developmental changes in nutrition and eating behavior.

Infancy

- The importance of adequate energy intake consumed in a loving and supportive environment in infancy cannot be overstated. The growing consensus is that breast feeding is better for the baby's health than bottle feeding.

Childhood

- Concerns about nutrition in childhood focus on excessive consumption of dietary fat and rates of obesity in middle and late childhood. Thirty percent of U.S. children are at risk for being overweight. Obesity increases a child's risk of developing many medical and psychological problems. Poor nutrition in children from low-income families is a special concern.

Adolescence

Adult Development and Aging

- Poor nutrition and being overweight are also key problems among adolescents. Anorexia nervosa, bulimia nervosa, and binge eating disorder can develop in adolescence; most anorexics, bulimics, and individuals with binge eating disorder are females.
- Obesity is a major concern throughout adulthood, and dieting is pervasive. Calorie restriction is associated with longevity in many animal studies, but a recent longitudinal study did not find greater longevity for calorie-restricted monkeys. Recent research reviews have found that antioxidant supplements do not reduce the risk for many diseases, such as cancer and cardiovascular disease.

3 Exercise

LG3 Summarize the roles of exercise in child and adult health.

Childhood and Adolescence

Adulthood

Aging and Longevity

- Most children and adolescents are not getting nearly enough exercise.
- Both moderate and intense exercise produce physical and psychological advantages such as reduced rates of heart disease and anxiety.
- Regular exercise in middle-aged and older adults can promote health and increase longevity.

4 Substance Use

LG4 Evaluate substance use in adolescence and adulthood.

Adolescence and Emerging Adulthood

Substance Use in Older Adults

- The United States has one of the highest adolescent drug use rates of any industrialized country. Alcohol and cigarette smoking are special concerns. Development, parents, peers, and educational success play important roles in preventing drug abuse in adolescents. Forty percent of U.S. college students say they drink heavily. Substance use peaks in emerging adulthood and then often decreases by the mid-twenties.
- Alcohol use declines in older adults, although abuse is more difficult to detect in older adults than in younger adults. There is concern about older adults who abuse prescription drugs and illicit drugs.

preview

Think about what is required for us to find our way around our environment, to play sports, or to create art. These activities require both active perception and precisely timed motor actions. Neither innate, automatic movements nor simple sensations are enough to let us do the things we take for granted every day. How do we develop perceptual and motor abilities, and what happens to them as we age? In this chapter, we will focus first on the development of motor skills, then on sensory and perceptual development, and finally on the coupling of perceptual-motor skills.

1 Motor Development

LG1 Describe how motor skills develop.

- The Dynamic Systems View
- Reflexes
- Gross Motor Skills
- Fine Motor Skills

Most adults are capable of coordinated, purposive actions of considerable skill, including driving a car, playing golf, and typing accurately on a computer keyboard. Some adults have extraordinary motor skills, such as those involved in winning an Olympic pole vault competition, painting a masterpiece, or performing heart surgery. Look all you want at a newborn infant, and you will observe nothing even remotely approaching these skilled actions. How, then, do the motor behaviors of adults come about?

THE DYNAMIC SYSTEMS VIEW

Developmentalist Arnold Gesell (1934) thought his painstaking observations had revealed how people develop their motor skills. He had discovered that infants and children develop rolling, sitting, standing, and other motor skills in a fixed order and within specific time frames. These observations, said Gesell, show that motor development comes about through the unfolding of a genetic plan, or maturation.

Later studies, however, demonstrated that the sequence of developmental milestones is not as fixed as Gesell indicated and not due as much to heredity as Gesell argued (Rachwani, Hoch, & Adolph, 2021). In the past two decades, the study of motor development experienced a renaissance as psychologists attained new insights about *how* motor skills develop (Adolph & Hoch, 2021). One increasingly influential perspective is dynamic systems theory, proposed by Esther Thelen (Thelen & Smith, 1998, 2006).

According to **dynamic systems theory,** infants assemble motor skills for perceiving and acting (Thelen & Smith, 2006). To develop motor skills, infants must perceive something in the environment that motivates them to act and then use their perceptions to fine-tune their movements. Motor skills represent pathways to the infant's goals (Adolph, 2018).

How is a motor skill developed, according to this theory? When infants are motivated to do something, they might create a new motor behavior. The new behavior results from many converging factors: the development of the nervous system, the body's physical properties and its possibilities for movement, the goal the child is motivated to reach, and environmental support for the skill. For example, babies learn to walk only when maturation of the nervous system allows them to control certain leg muscles, when their legs have grown enough to support their weight, and when they want to move.

Mastering a motor skill requires the infant's active efforts to coordinate several components of the skill. Infants explore and select possible solutions to the demands of a new task; they assemble adaptive patterns by modifying their current movement patterns. The first step occurs when the infant is motivated by a new challenge—such as the desire to cross a room—and gets into the "ballpark" of the task demands by taking a couple of stumbling steps. Then the infant "tunes" these movements to make them smoother and more effective. The tuning is achieved through repeated cycles of action and perception of the consequences of that action. According to the dynamic systems view, even universal milestones, such as crawling, reaching,

Esther Thelen (1941–2004) is shown conducting an experiment to discover how infants learn to control their arms to reach and grasp for objects. A computer device was used to monitor the infant's arm movements and to track muscle patterns. Thelen's research was conducted from a dynamic systems perspective. *What is the nature of this perspective?*

dynamic systems theory A theory proposed by Esther Thelen that seeks to explain how infants assemble motor skills for perceiving and acting.

How might dynamic systems theory explain the development of learning to walk?
Elizaveta Vladimerovna Koifman/123RF

and walking, are learned through this process of adaptation: Infants modulate their movement patterns to fit a new task by exploring and selecting possible configurations (Rachwani, Hoch, & Adolph, 2021).

To see how dynamic systems theory explains motor behavior, imagine that you offer a new toy to a baby named Gabriel (Thelen & others, 1993). There is no exact program that can tell Gabriel ahead of time how to move his arm and hand and fingers to grasp the toy. Gabriel must adapt to his goal—grasping the toy—and the context. From his sitting position, he must make split-second adjustments to extend his arm, holding his body steady so that his arm and torso don't plow into the toy. Muscles in his arm and shoulder contract and stretch in a host of combinations, exerting a variety of forces. He improvises a way to reach out with one arm and wrap his fingers around the toy.

Thus, according to dynamic systems theory, motor development is not a passive process in which genes dictate the unfolding of a sequence of skills over time. Rather, the infant actively puts together a skill to achieve a goal within the constraints set by the infant's body and environment (Kyvelidou & Stergiou, 2019). Nature and nurture, the infant and the environment, work together as part of an ever-changing system (Van Hooren, Meijer, & McCrum, 2019).

Recently, Karen Adolph and Justine Hoch (2019) described four key aspects that reflect the dynamic systems theory of motor development: (1) embodied, (2) embedded, (3) enculturated, and (4) enabling.

- *Motor Development Is Embodied.* Opportunities for motor behavior involve the current status of a child's body. Changes in infants' bodies modify the nature of their motor behavior. Walking is a good example of motor behavior being embodied. Over weeks and months of walking experiences, infants improve their walking skills. Initially, they walk very slowly in halting, inconsistent ways and have poor balance. With extensive experiences, they walk faster, their steps become more consistent, and they have much better balance. Their changing body interacts with experiences and opportunities to walk as they physically grow.
- *Motor Development Is Embedded.* Environmental circumstances can facilitate or restrict possibilities for motor behavior. Motor behavior occurs in a physical environment and a changing world. Variations in the environment require infants to be flexible and adapt to these changing circumstances. As they encounter steep slopes, narrow passageways, stairs, and many other variations in their physical environment, infants must be flexible and modify how they move.
- *Motor Development Is Enculturated.* Social and cultural contexts influence motor behavior. Caregivers play important roles in infants' motor development. For example, caregivers often hold infants' hands and "walk" them around a room. And infants' first steps in learning to walk are likely in a social context as they go toward a caregiver's open arms. Cultures also vary in how much caregivers engage in behavior that stimulates and encourages infants' and children's motor development.
- *Motor Development Is Enabling.* Motor development is not isolated from other aspects of development, and it contributes to infants' and children's development in other domains. Motor development allows infants and children to explore and learn about much wider and more complex aspects of the environment. Before infants learn to crawl and walk, their exploration of the world depends on where their caregivers place them, but their expanding motor skills provide them with more independence in exploring and learning about the world, thereby advancing their cognitive and socioemotional development.

As you learn about the course of motor development, you will see how dynamic systems theory applies to some specific skills. First, though, let's examine how the story of motor development begins with reflexes.

developmental **connection**
Nature and Nurture
The epigenetic view states that development is an ongoing, bidirectional interchange between heredity and the environment. Connect to "Biological Beginnings."

rooting reflex A newborn's built-in reaction that occurs when the infant's cheek is stroked or the side of the mouth is touched. In response, the infant turns its head toward the side that was touched, in an apparent effort to find something to suck.

sucking reflex A newborn's automatic sucking when an object is placed in its mouth. The sucking reflex enables the infant to get nourishment before it has begun to associate a nipple with food.

Moro reflex A startle response that occurs in reaction to a sudden, intense noise or movement. When startled, the newborn arches its back, throws its head back, and flings out its arms and legs. Then the newborn rapidly closes its arms and legs to the center of the body.

grasping reflex A reflex that occurs when something touches an infant's palms. The infant responds by grasping tightly.

gross motor skills Motor skills that involve large-muscle activities, such as walking.

REFLEXES

Newborn infants are not completely helpless. Among other things, they have some basic reflexes. For example, when they are submerged, they will hold their breath and contract their throat to keep water out. Reflexes allow infants to respond adaptively to their environment before they have had the opportunity to learn.

The rooting and sucking reflexes are important examples. Both have survival value for newborn mammals, who must find a mother's breast to obtain nourishment. The **rooting reflex** occurs when an infant's cheek is stroked or the side of the mouth is touched. In response, the infant turns its head toward the side that was touched in an apparent effort to find something to suck. The **sucking reflex** occurs when newborns suck an object placed in their mouth. This reflex enables newborns to get nourishment before they have associated a nipple with food; it also serves as a self-soothing or self-regulating mechanism.

Another example is the **Moro reflex,** which occurs in response to a sudden, intense noise or movement (see Figure 1). When startled, newborns arch their back, throw back their head, and fling out their arms and legs. Then they rapidly close their arms and legs. The Moro reflex is believed to be a way of grabbing for support while falling, because it would have had survival value for our primate ancestors.

Some reflexes—coughing, sneezing, blinking, shivering, and yawning, for example—persist throughout life. They are as important for adults as they are for infants. Other reflexes, though, disappear several months following birth, as the infant's brain matures and voluntary control over many behaviors develops. The rooting and Moro reflexes, for example, tend to disappear when the infant is 3 to 4 months old.

The movements of some reflexes eventually become incorporated into more complex, voluntary actions. One important example is the **grasping reflex,** which occurs when something touches the infant's palms (see Figure 1). The infant responds by grasping tightly. By the end of the third month, the grasping reflex diminishes, and the infant shows a more voluntary grasp. As its motor development becomes smoother, the infant will grasp objects, carefully manipulate them, and explore their qualities.

Individual differences in reflexive behavior appear soon after birth. For example, the sucking capabilities of newborns vary considerably. Some newborns are efficient at sucking forcefully and obtaining milk; others are not as adept and get tired before they are full. Most infants take several weeks to establish a sucking style that is coordinated with the way the mother is holding the infant, the way milk is coming out of the bottle or breast, and the infant's temperament (Blass, 2008).

The old view of reflexes portrayed them as exclusively genetic, built-in mechanisms that govern the infant's movements. The new perspective on infant reflexes is that they are not automatic or completely beyond the infant's control. For example, infants can deliberately control such movements as alternating their legs to make a mobile jiggle or change their sucking rate to listen to a recording (Adolph, 2018).

GROSS MOTOR SKILLS

Ask any parents about their baby, and sooner or later you are likely to hear about one or more advances in motor skills, such as "Cassandra just learned to crawl," "Jesse is finally sitting alone," or "Angela took her first step last week." Parents proudly announce such milestones as their children transform themselves from babies unable to lift their heads to toddlers who grab things off the grocery store shelf, chase a cat, and participate actively in the family's social life (Thelen, 2000). These milestones are examples of **gross motor skills,** skills that involve large-muscle activities such as moving one's arms and walking.

The Development of Posture How do gross motor skills develop? As a foundation, these skills require postural control (Rachwani & others, 2019). For example, to track moving objects, you must be able to control your head so you can stabilize your gaze; before you can walk, you must be able to balance on one leg.

Posture is more than just holding still and straight. Posture is a dynamic process that is linked with sensory information in the skin, joints, and muscles, which tell us where we are in space; in vestibular organs in the inner ear that regulate balance and equilibrium; and in vision and hearing (Thelen & Smith, 2006).

Newborn infants cannot voluntarily control their posture. Within a few weeks, though, they can hold their head erect, and soon they can lift their head while prone. By 2 months of age, babies can sit while supported on a lap or an infant seat, but they cannot sit independently until they are 6 or 7 months old. Standing also develops gradually during the first year of life. By about 8 to 9 months, infants usually learn to pull themselves up and hold onto a chair, and they often can stand alone by about 10 to 12 months.

What are some developmental changes in posture during infancy?

Newly crawling infant

Experienced walker

FIGURE 2

THE ROLE OF EXPERIENCE AND LEARNING IN CRAWLING AND WALKING INFANTS' JUDGMENTS OF WHETHER TO GO DOWN A SLOPE. Karen Adolph (1997) found that locomotor experience rather than age was the primary predictor of adaptive responding on slopes of varying steepness. Newly crawling and walking infants could not judge the safety of the various slopes. With experience, they learned to avoid slopes where they would fall. When expert crawlers began to walk, they again made mistakes and fell, even though they had judged the same slope accurately when crawling. Adolph referred to this as the specificity of learning because it does not transfer across crawling and walking.

Courtesy of Dr. Karen Adolph, New York University

A baby is an angel whose wings decrease as his legs increase.

–French Proverb

Learning to Walk Locomotion and postural control are closely linked, especially in walking upright (Adolph & Hoch, 2021). Even young infants can make the alternating leg movements that are needed for walking. The neural pathways that control leg alternation are in place from a very early age, even at birth or before. Indeed, researchers have found that alternating leg movements occur during the fetal period and at birth (Adolph, 2018).

If infants can produce forward stepping movements so early, why does it take them so long to learn to walk? The key skills in learning to walk appear to be stabilizing balance on one leg long enough to swing the other forward and shifting the weight without falling. This is a difficult biomechanical problem to solve, and it takes infants about a year to do it.

In learning to locomote, infants must discover what kinds of places and surfaces are safe for crawling or walking (Rachwani, Hoch, & Adolph, 2021). Karen Adolph (1997) investigated how experienced and inexperienced crawling and walking infants go down steep slopes (see Figure 2). Newly crawling infants, who averaged about 8 months of age, rather indiscriminately went down the steep slopes, often falling in the process (with their mothers standing next to the slope to catch them). After weeks of practice, the crawling babies became more adept at judging which slopes were too steep to crawl down and which ones they could navigate safely.

Thus, practice and learning are very important in the development of new motor skills (Adolph & Hoch, 2021). In one study, Adolph and her colleagues (2012) observed 12- to 19-month-olds during free play. Locomotor experience was extensive, with the infants averaging 2,368 steps and 17 falls per hour.

Might the development of walking be linked to advances in other aspects of development? Walking experience leads to being able to gain contact with objects that were previously out of reach and to initiate interaction with parents and other adults, thereby promoting language development (Adolph & Hoch, 2019; Walle & Campos, 2014). Thus, just as with advances in postural skills, walking skills can produce a cascade of changes in the infant's development.

The First Year: Motor Development Milestones and Variations Figure 3 summarizes important accomplishments in gross motor skills during the first year, culminating in the ability to walk easily. The timing of these milestones, especially the later ones, may vary by as much as two to four months, and experiences can modify the onset of these accomplishments (Adolph & Hoch, 2021). For example, in the early 1990s, pediatricians began recommending that parents place their babies on their backs to sleep. Following that instruction, babies who back-sleep began crawling later, typically several weeks later than babies who sleep prone (Davis & others, 1998). Also, some infants do not follow the standard sequence of motor accomplishments (Eaton & others, 2008). For example, many American infants never crawl on their belly or on their hands and knees. They might discover an idiosyncratic form of locomotion before walking, such as rolling, or they might never locomote until they get upright. In Jamaica, approximately one-fourth of babies skip crawling altogether (Hopkins, 1991).

The early view that growth and motor development simply reflect the age-related output of maturation is, at best, incomplete (Lampl, 2021). Rather, infants develop new skills with the guidance of their caregivers in a real-world environment of objects, surfaces, and planes (Rachwani, Hoch, & Adolph, 2021).

Development in the Second Year The motor accomplishments of the first year bring increasing independence, allowing infants to explore their environment more extensively and to initiate interaction with others more readily. In the second year of life, toddlers become more motorically skilled and mobile (Adolph, Rachwani, & Hoch, 2019). Motor activity during the second year is vital to the child's competent development, and few restrictions, except for safety, should be placed on their adventures.

By 13 to 18 months, toddlers can pull a toy attached to a string and use their hands and legs to climb up a number of steps. By 18 to 24 months, toddlers can walk quickly or run stiffly for a short distance, balance on their feet in a squatting position while playing with objects on the floor, walk backward without losing their balance, stand and kick a ball without falling, stand and throw a ball, and jump in place.

Can parents give their babies a head start on becoming physically fit and physically talented through structured exercise classes? Most infancy experts recommend against structured

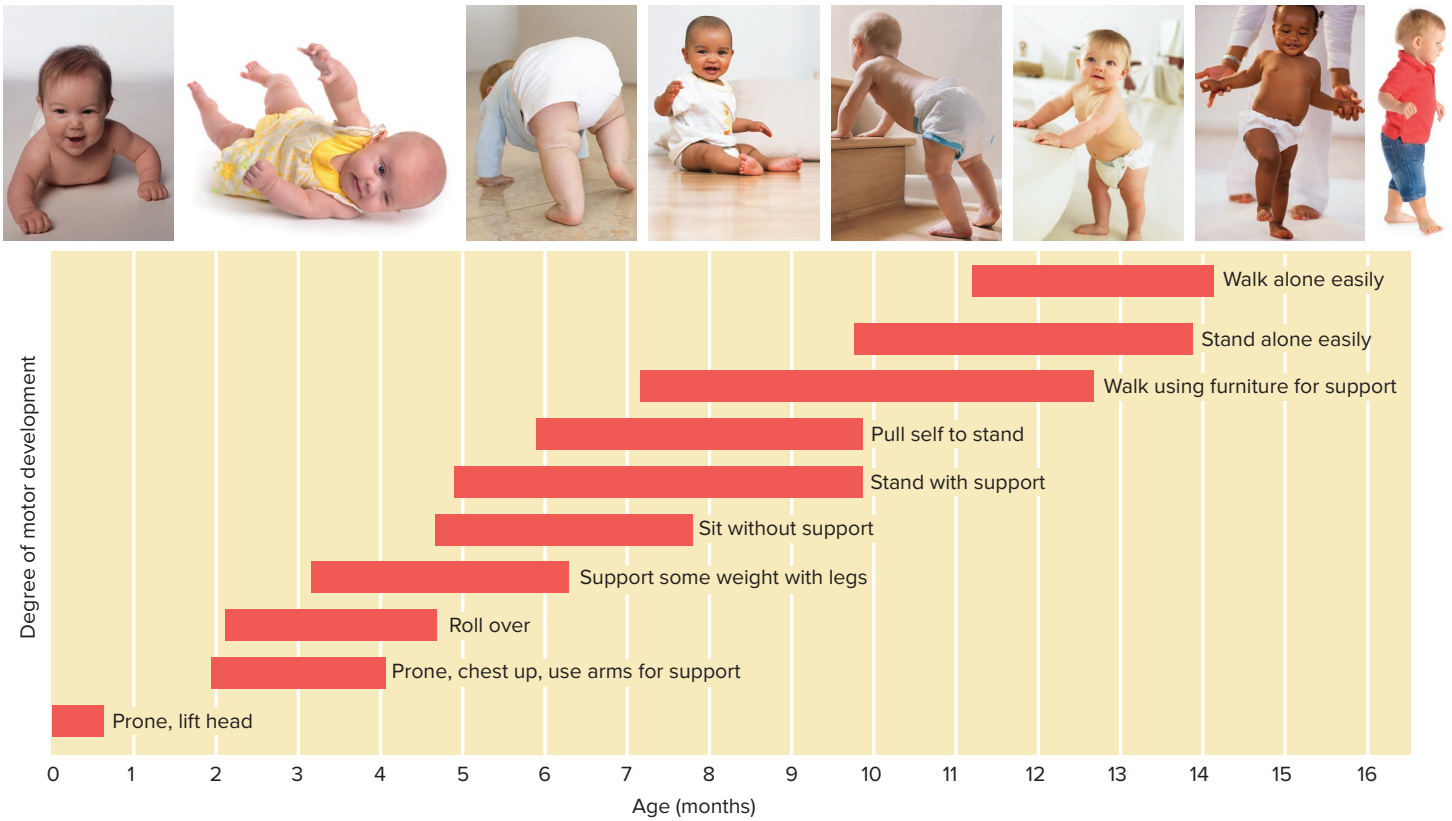

FIGURE 3

MILESTONES IN GROSS MOTOR DEVELOPMENT. The horizontal red bars indicate the range in which most infants reach various milestones in gross motor development.

(*Left to right*): Barbara Penoyar/Photodisc/Getty Images; Benjamin Simeneta/Shutterstock; Image Source/Alamy Stock Photo; Victoria Blackie/Photodisc/Getty Images; Cohen/Ostrow/Digital Vision/Getty Images; Fotosearch/Getty Images; Tom Grill/Fuse/Getty Images; Monika Wisniewska/Amaviael/123RF

exercise classes for babies. But there are other ways to guide infants' motor development. Caregivers in some cultures do handle babies vigorously, and such treatment might advance motor development, as we discuss next.

Cultural Variations in Guiding Infants' Motor Development Mothers in developing countries tend to stimulate their infants' motor skills more than mothers in more developed countries (Hopkins, 1991). In many African, Indian, and Caribbean cultures, mothers massage and stretch their infants during daily baths (Adolph, Karasik, & Tamis-LeMonda, 2010). Mothers in the Gusii culture of Kenya also encourage vigorous movement in their babies.

Do these cultural variations make a difference in motor development? When caregivers provide babies with physical guidance by physically handling them in special ways (such as stroking, massaging, or stretching) or by giving them opportunities for exercise, the infants often reach motor milestones earlier than infants whose caregivers have not provided these activities (Adolph, Cole, & Vereijken, 2015; Adolph, Karasik, & Tamis-LeMonda, 2010). For example, Jamaican mothers expect their infants to sit and walk alone two to three months earlier than English mothers do (Hopkins & Westra, 1990). And in sub-Saharan Africa, traditional practices in many villages involve mothers and siblings engaging babies in exercises, such as frequent exercise for trunk and pelvic muscles (Super & Harkness, 2010).

Practices that restrain infants' movement–such as Chinese sandbags, orphanage restrictions, and failure of caregivers to encourage movement in Budapest–have been found to produce substantial delays in motor development (Adolph, Karasik, & Tamis-LeMonda, 2010). In some rural Chinese provinces, for example, babies are placed in a bag of fine sand, which acts as a diaper and is changed once a day. The baby is left alone, face up, and is visited only when being fed by the mother (Xie & Young, 1999). Some studies of swaddling show slight delays

(*Left*) In the Algonquin culture in Quebec, Canada, babies are strapped to a cradle board for much of their infancy. (*Right*) In Jamaica, mothers massage and stretch their infants' arms and legs. *To what extent do cultural variations in the activity infants engage in influence the time at which they reach motor milestones?*
(*Left*): Danita Delimont/Alamy Stock Photo; (*right*): Pippa Hetherington/Earthstock/Newscom

in motor development, but other studies show no delays. Cultures that swaddle infants usually do so before the infant is mobile. When the infant becomes more mobile, swaddling decreases.

To close our discussion of motor development in infancy, it is important to highlight a key theme: infants' development of a skill, such as sitting, crawling or walking, requires considerable behavioral flexibility—the ability to do what is necessary to attain life's everyday goals (Adolph & Hoch, 2021). Adaptive behavior involves finding an accurate solution to a current situation and challenge. The infant's movements cannot be repeated in the same way over time and in different situations because their bodies, the environments in which they move, and the tasks they face change. Keep this theme in mind as you read about motor development in childhood next because such behavioral flexibility continues to be required for finding successful solutions to changing bodies, contexts, and tasks as children continue to develop.

What are some developmental changes in children's motor development in early childhood and middle and late childhood?
Mehmet zhan Araboga/EyeEm/Getty Images

Childhood The preschool child no longer has to make an effort to stay upright and to move around. As children move their legs with more confidence and carry themselves more purposefully, moving around in the environment becomes more automatic.

At 3 years of age, children enjoy simple movements, such as hopping, jumping, and running back and forth, just for the sheer delight of performing these activities. They take considerable pride in showing how they can run across a room and jump all of 6 inches. For the 3-year-old, such activity is a source of considerable pride in accomplishment.

At 4 years of age, children are still enjoying the same kinds of activities, but they have become more adventurous. They scramble over low jungle gyms as they display their athletic prowess.

At 5 years of age, children are even more adventuresome than they were at 4. It is not unusual for self-assured 5-year-olds to perform hair-raising stunts on practically any climbing object. They run hard and enjoy racing with each other and their parents.

During middle and late childhood, children's motor development becomes much smoother and more coordinated than it was in early childhood. For example, only one child in a thousand can hit a tennis ball over the net at the age of 3, yet by age 10 or 11 most children can learn to play the sport. Running, climbing, skipping rope, swimming, bicycle riding, and skating are just a few of the many physical skills elementary school children can master. And, when mastered, these physical skills are a source of great pleasure and a sense of accomplishment. In gross motor skills involving large-muscle activity, boys usually outperform girls.

Just as in infancy, goal-directed actions involve problem-solving that requires perception and action to be coordinated. Recent research examined how preschool children and adults inserted three-dimensional objects into their corresponding openings in a box (Ossmy & others, 2020). Preschool children and adults solved the problem successfully. However, adults did so much faster, and the faster speed was linked to adjusting an object's orientation while moving it toward the box while the young children adjusted the object's orientation after they brought it to the box. The children's slower speed also was influenced by looking at the object's shape and the corresponding opening in the box. This research indicated that planning involves a real-time cascade of perception and action, and in this task looking served as the basis for planning actions.

There can be long-term negative effects for children who fail to develop basic motor skills (Dinkel & Snyder, 2020). These children will not be as able to join in group games or participate in sports during their school years and in adulthood. In one study, children with a low level of motor competence had a lower motivation for sports participation and had lower global self-worth than their counterparts with a high level of motor competence (Bardid & others, 2016). Another study found that higher motor proficiency in preschool was linked with engaging in a higher level of physical activity in adolescence (Venetsanou & Kambas, 2017).

Organized sports are one way of encouraging children to be active and to develop their motor skills. Schools and community agencies offer programs for children that involve baseball, soccer, football, basketball, swimming, gymnastics, and other sports. For children who participate in them, these programs may play a central role in their lives.

Participation in sports can have both positive and negative consequences for children (Hosseinzadeh & Kiapour, 2020). Participation can provide exercise, opportunities to learn how to compete, enhanced self-esteem, persistence, and a setting for developing peer relations and friendships (Theokas, 2009). Further, recent research indicates that participating in sports reduces the likelihood that children will become obese (Learmonth & others, 2019). Another study revealed that children who play sports show a lower cardiovascular risk profile (Hebert & others, 2017). In addition, a recent study of urban, predominantly Latinx 6- to 11-year-olds found that playing fewer sports was linked to increased symptoms of withdrawal and depression (Matta & others, 2021). Thus, participating in sports might protect against symptoms of depression in children. And in a recent study of out-of-school activities, time spent in organized sports was associated with increased positive self-identity (Lee & others, 2018).

However, sports also can bring pressure to achieve and win, physical injuries, a distraction from academic work, and unrealistic expectations for success as an athlete (Smith, Krejany, & Jiwa, 2021; Sokka & others, 2020). There is increasing concern about the occurrence of concussions in youth football and soccer (Waltzman & others, 2020; Zimmerman & others, 2021). The *Connecting Development to Life* interlude examines the roles of parents and coaches in children's sports.

Health

Exercise is linked to prevention and effective treatment of many diseases. Connect to "Health."

Adolescence and Adulthood Gross motor skills typically improve during adolescence. Most of us reach our peak physical performance before the age of 30, often between the ages of 19 and 26. This peak occurs both for the average young adult and for outstanding athletes. Even though athletes keep getting better than their predecessors—running faster, jumping higher, and lifting more weight—the age at which they reach their peak performance has remained virtually unchanged (Schultz & Curnow, 1988). Most swimmers and gymnasts reach their peak in their late teens. Many athletes, including track performers in sprint races (100- and 200-yard dashes), peak in their early to mid-twenties. Golfers and marathon runners tend to peak in their late twenties or even early thirties.

After an individual reaches the age of 30, most biological functions begin to decline, although the decline of specific organs can vary considerably. The decline in general biological functioning that begins at about age 30 occurs at a rate of about 0.75 to 1 percent a year. Declines often occur in cardiovascular functioning, muscle strength, bone density (especially for females), neural function, balance, and flexibility.

Older adults move more slowly than young adults, and this slowing occurs for movements with a wide range of difficulty (Davis & others, 2013) (see Figure 4). Even when they perform everyday tasks such as reaching and grasping, moving from one place to another, and continuous movement, older adults tend to move more slowly than they did when they were young (Koon & others, 2020). Adequate mobility is an important aspect of maintaining an independent

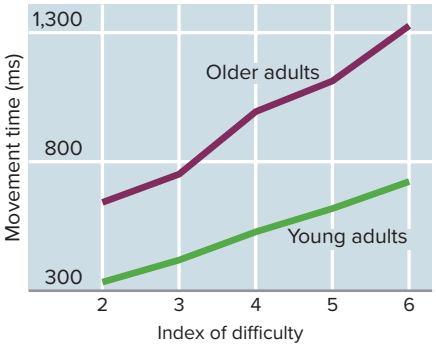

FIGURE **4**

MOVEMENT AND AGING. Older adults take longer to move than young adults, and this change occurs across a range of movement difficulty (Ketcham & Stelmach, 2001).

connecting development to life

Parents, Coaches, and Children's Sports

Most sports psychologists stress that it is important for parents to show an interest in their children's sports participation. Most children want their parents to watch them perform in sports. Many children whose parents do not come to watch them play in sporting events feel that their parents do not adequately support them. However, some children become extremely nervous when their parents watch them perform, or they get embarrassed when their parents cheer too loudly or make a fuss. If children request that their parents not watch them perform, parents should respect their children's wishes (Schreiber, 1990).

Parents should praise their children for their sports performance, and if they don't become overinvolved, they can help their children build their physical skills and guide them emotionally by discussing with them how to deal with a difficult coach, how to cope with a tough loss, and how to put in perspective a poorly played game. The following guidelines provided by the Women's Sports Foundation (2001) in its booklet *Parents' Guide to Girls' Sports* can benefit both parents and coaches of children in sports.

What are some of the possible positive and negative aspects of children's participation in sports?
(Top): kali9/Getty Images; *(bottom):* BananaStock/Alamy Stock Photo

The Dos

- Make sports fun; the more children enjoy sports, the more they will want to play.
- Remember that it is okay for children to make mistakes; it means they are trying.
- Allow children to ask questions about the sport and discuss the sport in a calm, supportive manner.
- Show respect for the child's sports participation.
- Be positive and convince the child that he or she is making a good effort.
- Be a positive role model for the child in sports.

The Don'ts

- Yell or scream at the child.
- Condemn the child for poor play or continue to bring up failures long after they happen.
- Point out the child's errors in front of others.
- Expect the child to learn something immediately.
- Expect the child to become a pro.
- Ridicule or make fun of the child.
- Compare the child to siblings or to more talented children.
- Make sports all work and no fun.

What developmental theories offer support for the Women's Sports Foundation's assertion that parents should strive to be positive role models for their children in sports?

and active lifestyle in late adulthood (Bland & others, 2021; Grosicki & others, 2020). Further, one study revealed that middle-aged and older adults who had limited mobility had lower cognitive functioning (Demnitz & others, 2018).

Recent research connects obesity with mobility limitation in older adults (Adair, Duazo, & Borja, 2018). In one study, researchers found that a combined program of physical activity and weight loss helped to preserve mobility in older, obese adults in poor cardiovascular health (Rejeski & others, 2011). Further, a recent large-scale study of older adults indicated that a 554-step-per-day increase in mobility reduced physical function limitations by 5.9 percent and improved quality of life by 3.2 percent (Kabiri & others, 2018).

The risk of falling in late adulthood increases with age and is greater for women than for men (Li & Harmer, 2020). Two-thirds of older adults who experience a fall are likely to fall again in the next six months. Falls are the leading cause of injury deaths among adults who are 65 years and older (National Center for Health Statistics, 2021). Each year, approximately 200,000 adults over the age of 65 (many of them women) fracture a hip in a fall. Half of these

older adults die within 12 months, frequently from pneumonia. Also, in a recent study, when older adults experienced a second hip fracture, it decreased how long they would live (Trevisan & others, 2020). In another study, high-intensity walking training reduced older adults' frailty, increased their walking speed, and improved their balance (Danilovich, Conroy, & Horby, 2018). Further, recent research indicated that proprioceptive training (balancing on one leg or walking toe to heal in a straight line, for example) reduced falls and increased balance and mobility in older adults (Espejo-Antunez & others, 2020). And in another recent study, exergames improved the mobility and balance of older adults (Pacheco & others, 2020).

Decreased walking speed in older adults is associated with limited mobility, less participation in community activities, greater cognitive decline, and increased risk of falls. A recent study of older women found that on average a reduction in walking speed occurred at about 71 years of age (Noce Kirkwood & others, 2018). A recent study also found that older adults who walked slowly were more likely to have mild cognitive impairment (Rajtar-Zembaty & others, 2019).

Motor skills decline less in older adults who are active and biologically healthy. *What is the difference between chronological age and biological age?*

FINE MOTOR SKILLS

Whereas gross motor skills involve large-muscle activity, **fine motor skills** involve finely tuned movements. Buttoning a shirt, typing, or doing any task that requires finger dexterity demonstrates fine motor skills.

Infancy Infants have hardly any control over fine motor skills at birth, but newborns do have many components of what will become finely coordinated arm, hand, and finger movements. The onset of reaching and grasping marks a significant milestone in infants' increasing ability to interact with their surroundings (Chinn & others, 2019). During the first two years of life, infants refine how they reach and grasp (Eisner & Adam, 2021). Initially, infants reach by moving their shoulders and elbows crudely, swinging toward an object. Later, when infants reach for an object they move their wrists, rotate their hands, and coordinate their thumb and forefinger. Infants do not have to see their own hands in order to reach for an object (Clifton & others, 1993). Cues from muscles, tendons, and joints, not sight of the limb, guide reaching among 4-month-old infants.

Infants refine their ability to grasp objects by developing two types of grasps. Initially, infants grip with the whole hand, which is called the *palmer grasp* (Anekar & Bordoni, 2020). Later, toward the end of the first year, infants also grasp small objects with their thumb and forefinger, which is called the *pincer grip*. Their grasping system is very flexible. They vary their grip on an object depending on its size, shape, and texture, as well as the size of their own hands relative to the object's size. Infants grip small objects with their thumb and forefinger (and sometimes their middle finger too), whereas they grip large objects with all of the fingers of one hand or both hands.

A young girl using a pincer grip to pick up puzzle pieces.
Newstockimages/SuperStock

Perceptual-motor coupling is necessary for the infant to coordinate grasping (Keen, 2011). As they mature, infants use different perceptual systems to coordinate grasping. Four-month-old infants rely greatly on touch to determine how they will grip an object; 8-month-olds are more likely to use vision as a guide (Newell & others, 1989). This developmental change is efficient because vision lets infants preshape their hands as they reach for an object.

Experience plays a role in reaching and grasping (Sacrey & others, 2014). In one study, providing 3-month-olds who were not yet engaging in reaching behavior with reaching experiences was linked to increased object exploration and attention focusing skills at 15 months of age (Libertus, Joh, & Needham, 2016). Researchers have also found that short-term training involving practice of reaching movements increased both preterm and full-term infants' reaching for and touching objects (Cunha & others, 2016; Guimaraes & Tudella, 2015).

Amy Needham and her colleagues have used "sticky mittens" to enhance young infants' active grasping and manipulation of objects. In one study, 3-month-old infants participated in

fine motor skills Motor skills that involve finely tuned movements, such as any activity that requires finger dexterity.

FIGURE **5**

play sessions wearing "sticky mittens," which the researchers described as "mittens with palms that stuck to the edges of toys and allowed the infants to pick up the toys" (Needham, Barrett, & Peterman, 2002, p. 279) (see Figure 5). Infants who participated in sessions with the mittens grasped and manipulated objects earlier in their development than a control group of infants who did not receive the "mitten" experience. The experienced infants looked at the objects longer, swatted at them more during visual contact, and were more likely to mouth the objects. In one study, 5-month-old infants whose parents trained them to use the sticky mittens for 10 minutes a day over a two-week period showed advances in their reaching behavior at the end of the two weeks (Libertus & Needham, 2010).

Just as infants need to exercise their gross motor skills, they also need to exercise their fine motor skills (Wiesen, Watkins, & Needham, 2016). Especially when they can manage a pincer grip, infants delight in picking up small objects. Many develop the pincer grip and begin to crawl at about the same time, and infants of this age pick up virtually everything in sight, especially on the floor, and put the objects in their mouth. Thus, parents need to be vigilant in regularly monitoring what objects are within the infant's reach (Keen, 2005).

Rachel Keen (2011; Keen, Lee, & Adolph, 2014) emphasizes that tool use is an excellent context for studying problem solving in infants because tool use provides information about how infants plan to reach a goal. Researchers in this area have studied infants' intentional actions that range from picking up a spoon in different orientations to retrieving rakes placed inside tubes (Lockman, Tamis-LeMonda, & Adolph, 2021). One study explored motor origins of tool use by assessing developmental changes in banging movements in 6- to 15-month-olds (Kahrs, Jung, & Lockman, 2013). In this study, younger infants were inefficient and variable when banging an object, but by 1 year of age infants showed consistent straight up-and-down hand movements that resulted in precise aiming and consistent levels of force.

Might gross and fine motor skills early in infancy be related to later development? A recent study found that gross motor skills at 6 months of age were positively linked to communication skills at 2 years of age and that fine motor skills at 12 months of age were positively related to communication skills at 2 years of age (Valla & others, 2020).

Childhood and Adolescence As children get older, their fine motor skills improve (Misirliyan & Huynh, 2020). At 3 years of age, children have had the ability to pick up tiny objects between their thumb and forefinger for some time, but they are still somewhat clumsy at it. Three-year-olds can build surprisingly high block towers, each block placed with intense concentration but often not in a completely straight line. When 3-year-olds play with a form board or a simple puzzle, they are rather rough in placing the pieces. Even when they recognize the hole that a piece fits into, they are not very precise in positioning the piece. They often try to force the piece into the hole or pat it vigorously.

What are some developmental changes in children's fine motor skills?
Rollover/E+/Getty Images

By 4 years of age, children's fine motor coordination has become much more precise. Sometimes 4-year-old children have trouble building high towers with blocks because, in their desire to place each of the blocks perfectly, they may upset those already stacked. By age 5, children's fine motor coordination has improved further. Hand, arm, and fingers all move together under better command of the eye. Mere towers no longer interest the 5-year-old, who now wants to build a house or a church, complete with steeple, though adults may still need to be told what each finished project is meant to be.

Increased myelination of the central nervous system is reflected in the improvement of fine motor skills during middle and late childhood. Children use their hands more adroitly as tools. Six-year-olds can hammer, paste, tie shoes, and fasten clothes. By 7 years of age, children's hands have become steadier. At this age, children prefer a pencil to a crayon for printing, and reversal of letters is less common. Printing becomes smaller. At 8 to 10 years of age, children can use their hands independently with more ease and precision; children can now write rather than print words. Letter size becomes smaller and more even. At 10 to 12 years of age, children begin to show manipulative skills similar to the abilities of adults. The complex,

intricate, and rapid movements needed to produce fine-quality crafts or to play a difficult piece on a musical instrument can be mastered. Girls usually outperform boys in fine motor skills.

Earlier we mentioned that gross and fine motor skills in early infancy are linked to communication skills later in development. Researchers also have found that children's gross and fine motor skills are associated with cognitive function (Kim & others, 2018). For example, in a study of 9-year-old children, their gross and fine motor skills were associated with cognitive function in areas such as memory and processing speed, as well as better performance in math and reading comprehension (Geertsen & others, 2016). And in a recent study of 8- to 10-year-olds, better gross motor development was linked to a higher level of visual working memory (van der Fels & others, 2020).

Adult Development Fine motor skills may undergo some decline in middle and late adulthood as dexterity decreases, although for most healthy individuals, fine motor skills such as reaching and grasping continue to be performed in functional ways (Hoogendam & others, 2014). However, pathological conditions may result in weakness or paralysis of an individual's hands, in which case performance of fine motor skills may become impossible.

2 Sensory and Perceptual Development

LG2 Outline the course of sensory and perceptual development.

What Are Sensation and Perception? | The Ecological View | Visual Perception | Hearing | Other Senses | Intermodal Perception | Nature/Nurture and Perceptual Development

How do sensations and perceptions develop? Can newborn infants see? If so, what can they perceive? What about the other senses—hearing, smell, taste, touch, and pain? What are they like in the newborn, and how do they develop? How do sensation and perception change when adults become older? These are among the intriguing questions that we explore in this section.

WHAT ARE SENSATION AND PERCEPTION?

How does a newborn know that her mother's skin is soft rather than rough? How does a 5-year-old know what color his hair is? How does a 10-year-old know that a firecracker is louder than a cat's meow? Infants and children "know" these things because of information that comes through the senses. Without vision, hearing, touch, taste, smell, and other senses, we would be isolated from the world; we would live in dark silence, a tasteless, colorless, feeling-less void.

Sensation occurs when information interacts with sensory *receptors*—the eyes, ears, tongue, nostrils, and skin. The sensation of hearing occurs when waves of pulsating air are collected

sensation Reaction that occurs when information interacts with sensory receptors—the eyes, ears, tongue, nostrils, and skin.

How would you use the Gibsons' ecological theory of perception and the concept of affordance to explain the role that perception is playing in this baby's activity?
Oksana Kuzmina/Shutterstock

by the outer ear and conducted through the bones of the inner ear and the *cochlea*, where mechanical vibrations are converted into electrical impulses. Then the electrical impulses move to the *auditory nerve*, which transmits them to the brain. The sensation of vision occurs as rays of light contact the eyes and become focused on the *retina*, where light is converted into electrical impulses. Then the electrical impulses are transmitted by the *optic nerve* to the visual centers of the brain.

Perception is the interpretation of what is sensed. The air waves that contact the ears might be interpreted as noise or as musical sounds, for example. The physical energy transmitted to the retina of the eye might be interpreted as a particular color, pattern, or shape, depending on how it is perceived.

THE ECOLOGICAL VIEW

In recent decades, much of the research on perceptual development in infancy has been guided by the ecological view of Eleanor and James J. Gibson (E. Gibson, 1969, 1989, 2001; J. Gibson, 1966, 1979). They argue that we do not have to take bits and pieces of data from sensations and build up representations of the world in our minds. Instead, our perceptual system can select from the rich information that the environment itself provides (Wagman & Blau, 2020).

According to the Gibsons' **ecological view,** we directly perceive information that exists in the world around us. Perception brings us into contact with the environment in order to interact with and adapt to it (Adolph & Hoch, 2021). Perception is designed for action. Perception gives people such information as when to duck, when to turn their bodies to get through a narrow passageway, and when to put up their hands to catch something.

In the Gibsons' view, all objects and surfaces have **affordances,** which are opportunities for interaction offered by objects that fit within our capabilities to perform activities. A pot may afford you something to cook with, and it may afford a toddler something to bang. Adults immediately know when a chair is appropriate for sitting, when a surface is safe for walking, or when an object is within reach. We directly and accurately perceive these affordances by sensing information from the environment–the light or sound reflecting from the surfaces of the world–and from our own bodies through muscle receptors, joint receptors, and skin receptors (Adolph, Kaplan, & Kretch, 2021).

An important developmental question is "What affordances can infants or children detect and use?" In one study, for example, when babies who could walk were faced with a squishy waterbed, they stopped and explored it, then chose to crawl rather than walk across it (Gibson & others, 1987). They combined perception and action to adapt to the demands of the task.

Studying infants' perception has not been an easy task. What do you think some of the research challenges might be? The *Connecting with Research* interlude describes some of the ingenious ways researchers study infants' perception.

VISUAL PERCEPTION

Some important changes in visual perception that occur with aging can be traced to differences in how the eye itself functions over time. These changes in the eye's functioning influence, for example, how clearly we can see an object, whether we can differentiate its colors, at what distances, and in what light. But the differences between what a newborn sees and what a toddler or an adult sees go far beyond those that can be explained by changes in the eye's functioning, as we discuss in this section.

perception The interpretation of sensation.

ecological view The view proposed by the Gibsons that people directly perceive information in the world around them. Perception brings people in contact with the environment in order to interact with it and adapt to it.

affordances Opportunities for interaction offered by objects that fit within our capabilities to perform activities.

Infancy

Psychologist William James (1890/1950) called the newborn's perceptual world a "blooming, buzzing confusion." More than a century later, we can safely say that he was wrong (Maurer, 2021). Even the newborn perceives a world with some order. That world of the newborn, however, is far different from the one perceived by the toddler or the adult.

Visual Acuity and Face Perception

Just how well can infants see? At birth, the nerves and muscles and lens of the eye are still developing. As a result, newborns cannot see small things that are far away. The newborn's vision is estimated to be 20/240 on the well-known

How Do Scientists Study the Newborn's Perception?

Robert Fantz

Key Points:

- newborns' perception
- measures of infant perception
- increasing use of eye-tracking

Scientists have developed a number of research methods and tools sophisticated enough to examine the subtle abilities of infants and to interpret their complex actions (Bendersky & Sullivan, 2007).

Visual Preference Method

Robert Fantz (1963) was a pioneer in this effort. Fantz made an important discovery that advanced the ability of researchers to investigate infants' visual perception: Infants look at different things for different lengths of time. Fantz placed infants in a "looking chamber," which had two visual displays on the ceiling above the infant's head. An experimenter viewed the infant's eyes by looking through a peephole. If the infant was fixating on one of the displays, the experimenter could see the display's reflection in the infant's eyes. This arrangement allowed the experimenter to determine how long the infant looked at each display. Fantz (1963) found that infants only 2 days old look longer at patterned stimuli, such as faces and concentric circles, than at red, white, or yellow discs. Infants 2 to 3 weeks old preferred to look at patterns—a face, a piece of printed matter, or a bull's-eye—longer than at red, yellow, or white discs (see Figure 6). Fantz's research method—studying whether infants can distinguish one stimulus from another by measuring the length of time they attend to different stimuli—is referred to as the **visual preference method.**

Habituation and Dishabituation

Another way that researchers have studied infant perception is to present a stimulus (such as a sight or a sound) a number of times. If the infant decreases its response to the stimulus after several presentations, this change indicates that the infant is no longer interested in the stimulus. If the researcher now presents a new stimulus, the infant's response will recover—an indication that the infant can discriminate between old and new stimuli (Snyder & Torrence, 2008). **Habituation** is the name given to decreased responsiveness to a stimulus after repeated presentations of the stimulus. **Dishabituation** is the recovery of a habituated response after a change in stimulation. Newborn infants can habituate to repeated sights, sounds, smells, or touches (Rovee-Collier, 2004). Among the measures researchers use in habituation studies are sucking behavior (sucking stops when the young infant attends to a novel object), heart and respiration rates, and the length of time the infant looks at an object. Figure 7 shows the results of one study of habituation and dishabituation with newborns (Slater, Morison, & Somers, 1988).

High-Amplitude Sucking

To assess an infant's attention to sound, researchers often use a method called high-amplitude sucking. In this method, infants are given a nonnutritive nipple to suck, and the nipple is connected to a sound-generating system. The researcher computes a baseline high-amplitude sucking rate in a one-minute silent period. Following the baseline, presentation of a sound is made contingent on the rate of high-amplitude sucking. Initially babies suck frequently so the sound occurs often. Gradually, they lose interest in hearing the same sound so they begin to suck less often. Then the researcher changes the sound that is being presented. If the babies renew their vigorous

FIGURE 6

FANTZ'S EXPERIMENT ON INFANTS' VISUAL PERCEPTION. (*a*) Infants 2 to 3 weeks old preferred to look at some stimuli more than others. In Fantz's experiment, infants preferred to look at patterns rather than at color or brightness. For example, they looked longer at a face, a piece of printed matter, or a bull's-eye than at red, yellow, or white discs. (*b*) Fantz used a "looking chamber" to study infants' perception of stimuli.

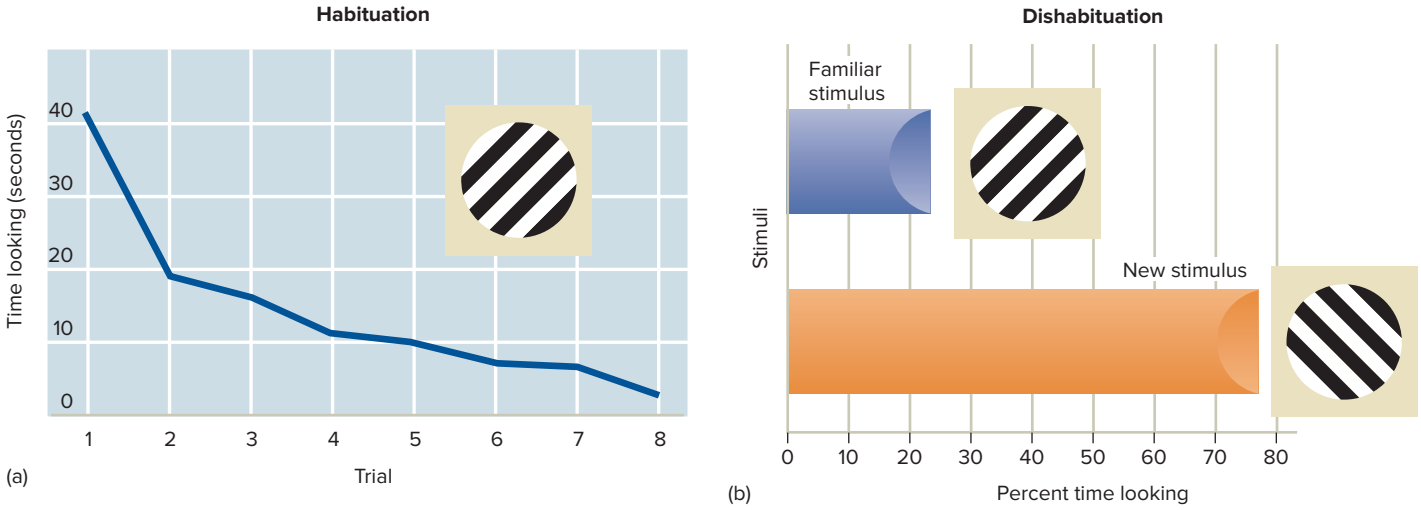

FIGURE 7

HABITUATION AND DISHABITUATION. In the first part of one study (*a*), 7-hour-old newborns were shown a stimulus. As indicated, the newborns looked at it an average of 41 seconds when it was first presented to them (Slater, Morison, & Somers, 1988). Over seven more presentations of the stimulus, they looked at it less and less. In the second part of the study (*b*), infants were presented with both the familiar stimulus to which they had just become habituated and a new stimulus (which was rotated 90 degrees). The newborns looked at the new stimulus three times as much as the familiar stimulus.

sucking, the inference is that they have noticed the sound change and are sucking more because they want to hear the interesting new sound (Menn & Stoel-Gammon, 2009).

The Orienting Response

A technique that can be used to determine whether an infant can see or hear is the orienting response, which involves turning one's head toward a sight or sound. Another technique, tracking, measures eye movements that follow (track) a moving object; it can be used to evaluate an infant's early visual ability. A startle response can be used to determine an infant's reaction to a noise (Bendersky & Sullivan, 2007).

Equipment

Technology can facilitate the use of most methods for investigating infants' perceptual abilities. Videotape equipment allows researchers to investigate elusive behaviors. High-speed computers make it possible to perform complex data analysis in minutes. Other equipment records respiration, heart rate, body movement, visual fixation, and sucking behavior, which provide clues to what the infant is perceiving.

The most important recent advance in measuring infant perception is the development of sophisticated eye-tracking equipment. Figure 8 shows an infant wearing eye-tracking headgear in a study on visually guided motor behavior and social interaction.

One of the main reasons that infant perception researchers are so enthusiastic about the recent availability of sophisticated eye-tracking equipment is that looking time is among the most important measures of infant perceptual and cognitive development (Aslin, 2012). The new eye-tracking equipment allows for much greater precision than human observation in assessing various aspects of

FIGURE 8

AN INFANT WEARING EYE-TRACKING HEADGEAR. Using the ultralight, wireless, head-mounted eye-tracking equipment shown here, researchers can record where infants look while the infants freely locomote. Most studies of infant eye-tracking now use remote optics eye trackers that have a camera that is not attached to the infant's head.

connecting with research (*continued*)

infant looking and gaze (Maylott & others, 2021). Among the areas of infant perception in which eye-tracking equipment is being used are attention (Macari & others, 2021), memory (Edgin & others, 2020), face processing (Bayet & others, 2021), intermodal perception (Ogren & Johnson, 2020), language (Avila-Varela, Arias-Trejo, & Mani, 2021), object categorization (LaTourrette & Waxman, 2019), and understanding of others' needs (Koster & others, 2019). Eye-tracking equipment also is improving our understanding of atypically developing infants, such as those who have autism (Achermann & others, 2021) or were born preterm (Imafuku & others, 2019).

Scientists have become ingenious at assessing the development of infants, discovering ways to "interview" them before they can talk. How might researchers account for any individual differences in infant development in their studies?

Snellen chart used for eye examinations, which means an object 20 feet away is only as clear to the newborn as it would be if it were 240 feet away from an adult with normal vision (20/20). By 6 months of age, though, average visual acuity is 20/40 (Aslin & Lathrop, 2008).

Faces are possibly the most important visual stimuli in children's social environment, and it is important that they extract key information from others' faces (Chen & others, 2021; Sirri & others, 2020). Infants show an interest in human faces soon after birth (Lee & others, 2013). Figure 9 shows a computer estimation of what a picture of a face looks like to an infant at different ages from a distance of about 6 inches. Infants spend more time looking at their mother's face than a stranger's face as early as 12 hours after being born (Bushnell, 2003). By 3 months of age, infants match voices to faces, distinguish between male and female faces, and discriminate between faces of their own ethnic group and those of other ethnic groups (Quinn, Lee, & Pascalis, 2019).

Experience plays an important role in face processing in infancy and later in development. One aspect of this experience involves the concept of *perceptual narrowing*, in which infants are more likely to distinguish between faces to which they have been exposed than faces that they have never seen before (Quinn & others, 2020).

Also, as we discussed in the *Connecting with Research* interlude, young infants can perceive certain patterns. With the help of his "looking chamber," Robert Fantz (1963) found that even 2- to 3-week-old infants prefer to look at patterned displays rather than nonpatterned displays. For example, they prefer to look at a normal human face rather than one with scrambled features, and they prefer to look at a bull's-eye target or black and white stripes rather than a plain circle.

visual preference method A method developed by Fantz to determine whether infants can distinguish one stimulus from another by measuring the length of time they attend to different stimuli.

habituation Decreased responsiveness to a stimulus after repeated presentations of the stimulus.

dishabituation The recovery of a habituated response after a change in stimulation.

Color Vision

The infant's color vision also improves over time (Atkinson & Braddick, 2013). By 8 weeks, and possibly as early as 4 weeks, infants can discriminate some colors (Kelly, Borchert, & Teller, 1997). By 4 months of age, they have color preferences that mirror those of adults in some cases, preferring saturated colors such as royal blue over pale blue,

FIGURE **9**

VISUAL ACUITY DURING THE FIRST MONTHS OF LIFE. The four photographs represent a computer estimation of what a picture of a face looks like to a 1-month-old, 2-month-old, 3-month-old, and 1-year-old (whose visual acuity approximates that of an adult).
Kevin Peterson/Photodisc/Getty Images

for example (Bornstein, 1975). In recent research, infants' looking times were greatest for blue hues and shortest for yellow-green hues (Skelton & Franklin, 2020). In part, the changes in vision described here reflect maturation. Experience, however, is also necessary for color vision to develop normally (Sugita, 2004).

Perceptual Constancy Some perceptual accomplishments are especially intriguing because they indicate that the infant's perception goes beyond the information provided by the senses (Johnson, 2020a, b). This is the case in perceptual constancy, in which sensory stimulation is changing but perception of the physical world remains constant. If infants did not develop perceptual constancy, each time they saw an object at a different distance or in a different orientation, they would perceive it as a different object. Thus, the development of perceptual constancy allows infants to perceive their world as stable. Two types of perceptual constancy are size constancy and shape constancy.

Size constancy is the recognition that an object remains the same even though the retinal image of the object changes as you move toward or away from the object. The farther away from us an object is, the smaller its image is on our eyes. Thus, the size of an object on the retina is not sufficient to tell us its actual size. For example, you perceive a bicycle standing right in front of you as smaller than the car parked across the street, even though the bicycle casts a larger image on your eyes than the car does. When you move away from the bicycle, you do not perceive it to be shrinking even though its image on your retinas shrinks; you perceive its size as constant. But what about babies? Do they have size constancy? Researchers have found that babies as young as 3 months of age show size constancy (Bower, 1966; Day & McKenzie, 1973). However, at 3 months of age, a baby's ability is not full-blown. It continues to develop until 10 or 11 years of age (Kellman & Banks, 1998).

Shape constancy is the recognition that an object remains the same shape even though its orientation to us changes. Look around the room you are in right now. You likely see objects of varying shapes, such as tables and chairs. If you get up and walk around the room, you will see these objects from different sides and angles. Even though your retinal image of the objects changes as you walk and look, you will still perceive the objects as the same shape.

Do babies have shape constancy? As with size constancy, researchers have found that babies as young as 3 months of age have shape constancy (Bower, 1966; Day & McKenzie, 1973). Three-month-old infants, however, do not have shape constancy for irregularly shaped objects such as tilted planes (Cook & Birch, 1984).

Perception of Occluded Objects Look again at the objects surrounding you. You likely see that some objects are partly occluded (hidden) by other objects that are in front of them—possibly a desk behind a chair, some books behind a computer, or a car parked behind a tree. Do infants perceive an object as complete when it is partly occluded by an object in front of it?

In the first two months of postnatal development, infants do not perceive occluded objects as complete, but instead perceive only what is visible (Johnson, 2020a, b). Beginning at about 2 months of age, infants develop the ability to perceive that occluded objects are whole (Slater & others, 2011). How does perceptual completion develop? In Scott Johnson's (2011, 2018, 2019, 2020a, b) research, learning, experience, and self-directed exploration via eye movements play key roles in the development of perceptual completion in young infants.

Depth Perception Might infants even perceive depth? To investigate this question, Eleanor Gibson and Richard Walk (1960) constructed a miniature cliff with a drop-off covered by glass. They placed infants on the edge of this visual cliff and had their mothers coax them to crawl onto the glass (see Figure 10). Most infants would not crawl out on the glass, choosing instead to remain on the shallow side, an indication that they could perceive depth. However, critics point out that the visual cliff likely is a better test of social referencing and fear of heights than of depth perception.

size constancy Recognition that an object remains the same even though the retinal image of the object changes as the viewer moves toward or away from the object.

shape constancy Recognition that an object remains the same even though its orientation to the viewer changes.

The 6- to 12-month-old infants in the visual cliff experiment had extensive visual experience. Do younger infants without this experience still perceive depth? Since younger infants do not crawl, this question is difficult to answer. Infants 2 to 4 months old show differences in heart rate when they are placed directly on the deep side of the visual cliff instead of on the shallow side (Campos, Langer, & Krowitz, 1970). However, these differences might mean that young infants respond to differences in some visual characteristics of the deep and shallow cliffs, with

no actual knowledge of depth (Adolph, Kaplan, & Kretch, 2021). Although researchers do not know exactly how early in life infants can perceive depth, we do know that infants develop the ability to use binocular cues to depth by about 3 to 4 months of age.

FIGURE **10**

EXAMINING INFANTS' DEPTH PERCEPTION ON THE VISUAL CLIFF. Eleanor Gibson and Richard Walk (1960) found that most infants would not crawl out on the glass, which, according to Gibson and Walk, indicated that they had depth perception. However, critics suggest that the visual cliff may be a better indication of the infant's social referencing and fear of heights than of the infant's perception of depth.

Childhood Changes in children's perceptual development continue in childhood (Grimm & others, 2019; Monier, Droit-Volet, & Coull, 2019). Children become increasingly efficient at detecting the boundaries between colors (such as red and orange) at 3 to 4 years of age (Gibson, 1969). When children are about 4 or 5 years old, their eye muscles usually are developed enough that they can move their eyes efficiently across a series of letters. Many preschool children are farsighted, unable to see close up as well as they can see far away. By the time they enter first grade, though, most children can focus their eyes and sustain their attention effectively on close-up objects.

What are the signs of vision problems in children? They include rubbing the eyes, blinking or squinting excessively, appearing irritable when playing games that require good distance vision, shutting or covering one eye, and tilting the head or thrusting it forward when looking at something. A child who shows any of these behaviors should be examined by an ophthalmologist.

After infancy, children's visual expectations about the physical world continue to develop. In one study, 2- to 4½-year-old children were given a task in which the goal was to find a ball that had been dropped through an opaque tube (Hood, 1995). As shown in Figure 11, if the ball is dropped into the tube at the top left, it will land in the box at the bottom right. However, in this task, most of the 2-year-olds, and even some of the 4-year-olds, persisted in searching in the box immediately beneath the dropping point. For them, gravity ruled and they had failed to perceive the end location of the curved tube. In two studies involving the task in Figure 11, 3-year-olds were able to overcome the gravity bias and their impulsive tendencies when they were given verbal instructions from a knowledgeable adult (Bascandziev & Harris, 2011; Joh, Jaswal, & Keen, 2011).

How do children learn to deal with situations like that in Figure 11, and how do they come to understand other laws of the physical world? These questions are addressed by studies of cognitive development, which we discuss in the chapters on "Cognitive Developmental Approaches" and "Information Processing."

FIGURE **11**

VISUAL EXPECTATIONS ABOUT THE PHYSICAL WORLD. When young children see the ball dropped into the tube, many of them will search for it immediately below the dropping point.

Adulthood Vision changes little after childhood until the effects of aging emerge (Meng & others, 2019). Seeing, hearing, and other aspects of sensory functioning are linked with our ability to perform everyday activities (Peng & others, 2019). Researchers have found that visual decline in late adulthood is linked to (a) cognitive decline (Lee & others, 2019), and (b) having fewer social contacts and engaging in less challenging social/leisure activities (Brunes, Hansen, & Heir, 2019; Cimarolli & others, 2017). For example, in a longitudinal study of individuals 60 years and older, visual and hearing difficulties predicted cognitive difficulties in verbal fluency, processing speed, and memory 8 years later (de la Fuente & others, 2019). In this study, the greatest cognitive decline occurred in individuals with both visual and hearing problems. With aging, declines occur in visual acuity, color vision, and depth perception. Several diseases of the eye also may emerge in aging adults.

Visual Acuity **Accommodation of the eye**—the eye's ability to focus and maintain an image on the retina—declines most sharply between 40 and 59 years of age. This loss of accommodation is what is commonly known as *presbyopia*. In particular, middle-aged individuals begin to have difficulty viewing close objects. The eye's blood supply also diminishes, although usually not until the fifties or sixties. The reduced blood supply may decrease the visual field's size and account for an increase in the eye's *blind spot*, the location where the retina does not register any light. And there is some evidence that the retina becomes less sensitive to low levels of illumination (Hughes, 1978). As a result, middle-aged adults begin to have difficulty reading or working in dim light. Presbyopia is correctable with bifocals, reading glasses, laser

What are some concerns about older adults' driving based on changes in visual perception?
Rike/Getty Images

surgery, or implantation of intraocular lenses. Indeed, laser surgery and implantation of intraocular lenses have become routine procedures for correcting vision in middle-aged adults (Ang & others, 2021).

In late adulthood, the decline in vision that began for most adults in early or middle adulthood becomes more pronounced. Visual processing speed declines in older adults (Bezdicek & others, 2016). Night driving is especially difficult, to some extent because of diminishing sensitivity to contrasts and reduced tolerance for glare (Kimlin, Black, & Wood, 2017). *Dark adaptation* is slower—that is, older individuals take longer to recover their vision when going from a well-lighted room to semidarkness. The area of the visual field becomes smaller, an indication that the intensity of a stimulus in the peripheral area of the visual field needs to be increased if the stimulus is to be seen. Events taking place away from the center of the visual field might not be detected (Anson & others, 2017).

This visual decline often can be traced to a reduction in the quality or intensity of light reaching the retina. At 60 years of age, the retina receives only about one-third as much light as it did at 20 years of age (Scialfa & Kline, 2007). In extreme old age, these changes might be accompanied by degenerative changes in the retina, causing severe difficulty in seeing. Large-print books and magnifiers might be needed in such cases.

Older adults also show a decline in motion sensitivity (Conlon & others, 2017). In terms of practical applications of this decline, researchers have found that compared with younger drivers, older drivers overestimate the time needed for an approaching vehicle to reach their location (Chevalier & others, 2017). This decline in the accuracy of effortless perceptual guidance means that older adult drivers need to expend cognitive effort when driving, especially when approaching intersections.

Color Vision Color vision also may decline with age in older adults as a result of the yellowing of the lens of the eye (Scialfa & Kline, 2007). This decline is most likely to occur in the green-blue-violet part of the color spectrum. As a result, older adults may have trouble accurately distinguishing between objects that are closely related in color, such as navy socks and black socks.

Depth Perception As with many areas of perception, depth perception changes little after infancy until adults become older. Depth perception typically declines in late adulthood, which can make it difficult for the older adult to determine how close or far away or how high or low something is (Bian & Andersen, 2008). A decline in depth perception can make steps or street curbs difficult to manage.

Diseases of the Eye Three diseases that can impair the vision of older adults are cataracts, glaucoma, and macular degeneration:

- **Cataracts** are a thickening of the lens of the eye that causes vision to become cloudy, opaque, and distorted. By age 70, approximately 30 percent of individuals experience a partial loss of vision due to cataracts. Diabetes is a risk factor for the development of cataracts (Greenberg & Bamba, 2021). Initially, vision impairment from cataracts can be minimized by wearing glasses; if cataracts worsen, a simple surgical procedure can remove the cloudy lens and replace it with an artificial one (Jackson, Edmiston, & Bedi, 2020). A recent Japanese study found that older adults (mean age: 76 years) who had cataract surgery were less likely to develop mild cognitive impairment than their counterparts who had not had the surgery (Miyata & others, 2018). Also, a recent study found that older adults with cataracts have a higher frequency of falls (Dos Santos Tavares & others, 2021).
- **Glaucoma** damages the optic nerve because of the pressure created by a buildup of fluid in the eye (Serbin & others, 2020). Approximately 1 percent of individuals in their seventies and 10 percent of those in their nineties have glaucoma, which can be treated with eye drops. If left untreated, glaucoma can ultimately destroy a person's vision.
- **Macular degeneration** is a disease that causes deterioration of the macula of the retina, which corresponds to the focal center of the visual field (see Figure 12). Individuals with macular degeneration may have relatively normal peripheral vision but be unable to see clearly what is directly in front of them (Heesterbeek & others, 2020; Ruia & Kaufman, 2021). Macular degeneration affects 1 in 25 individuals from 66 to 74 years of age and 1 in 6 of those 75 years old and older. If the disease is detected early, it can

FIGURE **12**

glaucoma Damage to the optic nerve because of pressure created by a buildup of fluid in the eye.

macular degeneration A vision problem in the elderly that involves deterioration of the macula of the retina.

be treated with laser surgery (Cohn & others, 2021). However, macular degeneration is difficult to treat and thus a leading cause of blindness in older adults (Zhu & others, 2019). One study found that macular degeneration was linked to increased risk of falls in adults 77 years and older (Wood & others, 2011). There is increased interest in using stem-cell based therapy to treat macular degeneration (de Jong & others, 2021).

HEARING

Can the fetus hear? What kinds of changes in hearing take place in infancy? When does hearing begin to decline in adulthood?

The Fetus, Infant, and Child During the last two months of pregnancy, as the fetus nestles in its mother's womb, it can hear sounds such as the mother's voice, music, and so on (Das & others, 2020). Two psychologists wanted to find out whether a fetus who heard Dr. Seuss' classic story *The Cat in the Hat* while still in the mother's womb would prefer hearing the story after birth (DeCasper & Spence, 1986). During the last months of pregnancy, 16 women read *The Cat in the Hat* to their fetuses. Then, shortly after the infants were born, the mothers read aloud either *The Cat in the Hat* or a story with a different rhyme and pace, *The King, the Mice and the Cheese* (which they had not read aloud during pregnancy). The infants sucked on a nipple in a different way when the mothers read the two stories, suggesting that they recognized the pattern and tone of *The Cat in the Hat* (see Figure 13). This study illustrates not only that a fetus can hear but also that it has a remarkable ability to learn even before birth. An fMRI study confirmed that the fetus can hear at 33 to 34 weeks by assessing fetal brain response to auditory stimuli (Jardri & others, 2012).

Infancy What changes in hearing take place during infancy? They involve perception of a sound's loudness, pitch, and localization (Cirelli & Trehub, 2021).

Immediately after birth, infants cannot hear soft sounds quite as well as adults can; a stimulus must be louder for the newborn to hear it (Trehub & others, 1991). By 3 months of age, infants' perception of sounds improves, although some aspects of loudness perception do not reach adult levels until 5 to 10 years of age (Trainor & He, 2013). Infants are also less sensitive to the pitch of a sound than adults are. *Pitch* is the frequency of a sound; a soprano voice sounds high-pitched, a bass voice low-pitched. Infants are less sensitive to low-pitched sounds and are more likely to hear high-pitched sounds (Aslin, Jusczyk, & Pisoni, 1998). By 2 years of age, infants have considerably improved their ability to distinguish between sounds with different pitches.

Even newborns can determine the general location from which a sound is coming, but by 6 months they are more proficient at *localizing* sounds, detecting their origins. The ability to localize sounds continues to improve during the second year (Werner, 2020). Although young infants can process variations in sound loudness, pitch, and localization, these aspects of hearing continue to improve through the childhood years (Trainor & He, 2013).

What are some concerns about adolescents who listen to loud music?
George Doyle/Stockbyte/Getty Images

Most children's hearing is adequate, but early hearing screening tests should be conducted during infancy, preferably in newborns (Bouillot, Vercherat, & Durand, 2019). About 1 in 1,000 newborns is deaf and 6 in 1,000 have some degree of hearing loss. Hearing aids or surgery can improve hearing for many of these infants (Halpin & others, 2010).

Adolescence Most adolescents' hearing is excellent. However, anyone who listens to loud sounds for sustained periods of time is at risk for the development of hearing problems. H.E.A.R. (Hearing Education and Awareness for Rockers) was founded by rock musicians whose hearing has been damaged by exposure to high-volume rock music. Increasingly, rock groups wear earplugs when they are playing loud music. Listening to loud music on iPods and MP3 players also can produce hearing problems. In a recent large-scale study of Korean adolescents, 17 percent had at least a slight hearing loss and this loss was associated with cumulative hours the adolescents had spent in gaming centers (Rhee & others, 2019). The adolescents' hearing loss also was related to lower academic performance (Rhee & others, 2019).

Adulthood and Aging Few changes in hearing are believed to take place during the adult years until middle adulthood (Vaden & others, 2017). Hearing can start to decline by the age of 40. Sensitivity to high pitches usually declines first. The ability to hear low-pitched sounds does not seem to decline much in middle adulthood, however. Men usually lose their sensitivity to high-pitched sounds sooner than women do, but this sex difference might be due to men's greater exposure to noise in occupations such as mining and automobile work.

Hearing impairment usually does not become much of an impediment until late adulthood (Pacala & Yeuh, 2012). A national survey revealed that 63 percent of adults 70 years and older had a hearing loss, defined as inability to hear sounds at amplitudes below 25 dB with their better ear (Lin & others, 2011). In this study, hearing aids were used by 40 percent of those with moderate hearing loss. Fifteen percent of the population over the age of 65 is estimated to be legally deaf, usually due to degeneration of the cochlea, the primary neural receptor for hearing in the inner ear (Adams, 2009). And in a study of 80- to 106-year-olds, there was a substantial increase in hearing loss in the ninth and tenth decades of life (Wattamwar & others, 2017).

Earlier, in discussing changes in vision, we considered research on the importance of the age of older adults in determining the degree of their visual decline. Age also is a factor in the degree of hearing decline in older adults (Hoffman & others, 2017). As indicated in Figure 14, the declines in vision and hearing are much greater in individuals 75 years and older than in individuals 65 to 74 years of age (Charness & Bosman, 1992).

Older adults often don't recognize that they have a hearing problem, deny that they have one, or accept it as a part of growing old (Pacala & Yeuh, 2012). Researchers have found that older adults' hearing problems are linked to impaired activities of daily living (Mueller-Schotte & others, 2019), less time spent out of home and in leisure activities (Mikkola & others, 2016), increased falls (Gopinath & others, 2016), reduced cognitive functioning (Armstrong & others, 2020), and increased loneliness (Mick & Pichora-Fuller, 2016). For example, in a recent study, hearing impairment was associated with accelerated cognitive decline in older adults (Alattar & others, 2019). In addition, a recent study found that initiation of hearing aid use in older adults was linked to either stable or improved executive function 18 months later (Sarant & others, 2020).

Two devices can minimize problems created by hearing loss: (1) hearing aids that amplify sound to reduce middle-ear-based conductive hearing loss, and (2) cochlear implants that restore some hearing following neurosensory hearing loss (Willink, Reed, & Lin, 2019). In a study of 80- to 106-year-olds mentioned previously, despite the universal loss of hearing in the 647 participants, only 59 percent of them wore hearing aids (Wattamwar & others, 2017). Researchers also are exploring implantation of stem cells as an alternative to cochlear implants (Tang, Hashino, & Nelson, 2020).

What outcomes occur when older adults have dual sensory loss in vision and hearing? In a recent study of 65- to 85-year-olds, dual sensory loss in vision and hearing was linked to reduced social participation and less social support, as well as increased loneliness (Mick & others, 2018). In another recent study, this type of dual sensory loss in older adults (mean age

Perceptual System	Young-Old (65 to 74 years)	Old-Old (75 years and older)
Vision	There is a loss of acuity even with corrective lenses. Less transmission of light occurs through the retina (half as much as in young adults). Greater susceptibility to glare occurs. Color discrimination ability decreases.	There is a significant loss of visual acuity and color discrimination, and a decrease in the size of the perceived visual field. In late old age, people are at significant risk for visual dysfunction from cataracts and glaucoma.
Hearing	There is a significant loss of hearing at high frequencies and some loss at middle frequencies. These losses can be helped by a hearing aid. There is greater susceptibility to masking of what is heard by noise.	There is a significant loss at high and middle frequencies. A hearing aid is more likely to be needed than in young-old age.

FIGURE **14**

VISION AND HEARING DECLINE IN THE YOUNG-OLD AND THE OLD-OLD.

of 82 years) involved greater functional limitations, increased loneliness, cognitive decline, and communication problems (Davidson & Gutherie, 2019). And in another recent study, older adults who had a dual sensory impairment involving vision and hearing had more depressive symptoms (Han & others, 2019).

OTHER SENSES

As we develop, we not only obtain information about the world from our eyes and our ears but also through sensory receptors in our skin, nose, and tongue.

Touch and Pain Do newborns respond to touch (called "tactile stimulation" by scientists)? Can they feel pain? How does the perception of touch and pain change with age?

Infancy Newborns do respond to touch (Bremner, 2021). A touch to the cheek produces a turning of the head; a touch to the lips produces sucking movements.

Regular gentle tactile stimulation prenatally may have positive developmental outcomes. For example, researchers found that 3-month-olds who had regular gentle tactile stimulation as fetuses were more likely to have an easy temperament than their counterparts who had irregular gentle or no tactile stimulation as fetuses (Wang, Hua, & Xu, 2015).

Newborns can also feel pain (Ilhan & others, 2020). If and when you have a son and consider whether he should be circumcised, the issue of an infant's pain perception probably will become important to you. When circumcision is performed during infancy, it usually takes place between the third and eighth days after birth. Will your young son experience pain if he is circumcised when he is 3 days old? An investigation by Megan Gunnar and her colleagues (1987) found that infant males cried intensely during circumcision. The circumcised infants also displayed amazing resiliency. Within several minutes after the surgery, they could nurse and interact in a normal manner with their mothers. And, if allowed to, the newly circumcised infants drifted into a deep sleep, which seemed to serve as a coping mechanism. Also, once researchers discovered that newborns feel pain, the practice of operating on newborns without anesthesia began to be reconsidered. Anesthesia is now used in some circumcisions (Morris & others, 2012).

A neuroimaging study revealed that the pain threshold in newborns occurs at a lower level of stimulation than for adults, confirming newborns' heightened pain sensitivity that has been found in earlier behavioral studies (Goksan & others, 2015). And in another study, kangaroo care was effective in reducing neonatal pain, especially indicated by significantly lower levels of crying when the care was instituted after the newborn's blood had been drawn by a heel stick (Seo, Lee, & Ahn, 2016).

Adulthood There has been little research on developmental changes in touch and pain after infancy until middle and late adulthood. Changes in touch and pain are associated with aging. A national study of community-dwelling older adults revealed that 70 percent of older adults had impaired touch (Correia & others, 2016). One study found that older adults could detect touch much less in the lower extremities (ankles, knees, and so on) than in the upper extremities (wrists, shoulders, and so on) (Corso, 1977). For most older adults, though, a decline in touch sensitivity is not problematic (Hoyer & Roodin, 2009).

An estimated 60 to 75 percent of older adults report at least some persistent pain (Molton & Terrill, 2014). The most frequent pain complaints of older adults are back pain (40 percent), peripheral neuropathic pain (35 percent), and chronic joint pain (15 to 25 percent) (Denard & others, 2010). The presence of pain increases with age in older adults, and women are more likely to report having pain than are men (Tsang & others, 2008). In a recent research review, it was concluded that older adults have lower pain sensitivity but only for lower pain intensities (Lautenbacher & others, 2017). Also, a recent study found that high levels of pain were linked to memory impairment in older adults (van der Leeuw & others, 2018).

Smell Newborns can differentiate odors (Doty & Shah, 2008). The expressions on their faces seem to indicate that they like the way vanilla and strawberry smell but do not like the way rotten eggs and fish smell (Steiner, 1979). In one investigation, 6-day-old infants who were breast fed showed a clear preference for smelling a breast pad that had been used by their mother rather than a clean breast pad (MacFarlane, 1975). However, when they were 2 days old, they did not show this preference, indicating that they require several days of experience to recognize this odor.

A decline in sensitivity to odors may occur as early as the twenties, with declines continuing through each subsequent decade of life into the nineties (Margran & Boulton, 2005). Beginning in the sixties, the decrease in sensitivity to smells becomes more noticeable to most people (Hawkes, 2006). A majority of individuals 80 years of age and older experience a significant reduction in smell (Lafreniere & Mann, 2009). A decline in the sense of smell can reduce the ability to detect smoke from a fire.

The decline in the olfactory system can reduce older adults' enjoyment of food and their life satisfaction. If elderly individuals need to be encouraged to eat more, compounds that stimulate the olfactory nerve are sometimes added to food.

Taste Sensitivity to taste is present even before birth (Doty & Shah, 2008). Human newborns learn tastes prenatally through the amniotic fluid and in breast milk after birth (Beauchamp & Mennella, 2009; Mennella, 2009). In one study, even at only 2 hours of age, babies made different facial expressions when they tasted sweet, sour, and bitter solutions (Rosenstein & Oster, 1988) (see Figure 15). At about 4 months of age, infants begin to prefer salty tastes, which as newborns they had found to be aversive (Doty & Shah, 2008).

Most older adults lose some of their sense of smell or taste, or both. A national study of community-dwelling older adults revealed that 74 percent had impaired taste and 22 percent had impaired smell (Correia & others, 2016). As with smell, there is less decline in taste in healthy older adults than in unhealthy older adults. However, when even relatively healthy older adults take medications, their taste sensitivity declines (Roberts & Rosenberg, 2006). Many older adults prefer highly seasoned foods (sweeter, spicier, saltier) to compensate for their diminished taste and smell (Hoyer & Roodin, 2009). This preference can lead to increased eating of nonnutritious, highly seasoned "junk food."

(a) (b) (c)

FIGURE **15**

NEWBORNS' FACIAL RESPONSES TO BASIC TASTES. Facial expressions elicited by (*a*) a sweet solution, (*b*) a sour solution, and (*c*) a bitter solution.
Rosenstein, D & Oster, H (1988) Differential facial responses to four basic tastes in newborns. Child Development, 59, p.1561

Researchers have found that older adults show a greater decline in their sense of smell than in their taste (Schiffman, 2007). Also, a recent study of older adults revealed that an inability to smell some odors, especially peppermint, was linked to cognitive decline (Liang & others, 2020). And, smell, too, declines less in healthy older adults than in their less healthy counterparts. Further, a recent study of adults 65 years of age and older found that those with olfactory dysfunction were likely to die earlier (Choi & others, 2021).

How is intermodal perception involved in this context in which a boy is listening to headphones while working on a computer?
Özgür Donmaz/Getty Images

INTERMODAL PERCEPTION

Imagine that you are playing basketball or tennis. You are experiencing many visual inputs—the ball is coming and going, other players are moving around, and so on. However, you are experiencing many auditory inputs as well: the sound of the ball bouncing or being hit, the grunts and groans of the other players, and so on. There is good correspondence between much of the visual and auditory information: When you see the ball bounce, you hear a bouncing sound; when a player stretches to hit a ball, you hear a groan. When you look at and listen to what is going on, you do not experience just the sounds or just the sights; you put all of these things together. You experience a unitary episode. This is **intermodal perception,** which involves integrating information from two or more sensory modalities, such as vision and hearing (Gergely & others, 2019). Most perception is intermodal (Bahrick, Lickliter, & Todd, 2021).

Early, exploratory forms of intermodal perception exist even in newborns (Bahrick & Hollich, 2008). For example, newborns turn their eyes and their head toward the sound of a voice or rattle when the sound is maintained for several seconds (Clifton & others, 1981), but the newborn can localize a sound and look at an object only in a crude way (Bechtold, Bushnell, & Salapatek, 1979). These early forms of intermodal perception become sharpened with experience in the first year of life (Kirkham & others, 2012). In one study, infants as young as 3½ months old looked more at their mother when they also heard her voice and longer at their father when they also heard his voice (Spelke & Owsley, 1979). Thus, even young infants can coordinate visual-auditory information about people.

Can young infants put vision and sound together as precisely as adults do? In the first six months, infants have difficulty connecting sensory input from different modes, but in the second half of the first year they show an increased ability to make this connection mentally.

NATURE/NURTURE AND PERCEPTUAL DEVELOPMENT

Now that we have discussed many aspects of perceptual development, let's explore one of developmental psychology's key issues as it relates to perceptual development: the nature-nurture issue. There has been a long-standing interest in how strongly infants' perception is influenced by nature or nurture (Johnson, 2020a, b; Slater & others, 2011). In the field of perceptual development, nature proponents are referred to as *nativists* and those who emphasize learning and experience are called *empiricists*.

In the nativist view, the ability to perceive the world in a competent, organized way is inborn or innate. A completely nativist view of perceptual development no longer is accepted in developmental psychology.

The Gibsons argued that a key question in infant perception is what information is available in the environment and how infants learn to generate, differentiate, and discriminate the information—certainly not a nativist view. The Gibsons' ecological view also is quite different from Piaget's constructivist view. According to Piaget, much of perceptual development in infancy must await the development of a sequence of cognitive stages for infants to construct more complex perceptual tasks. Thus, in Piaget's view the ability to perceive size and shape constancy, a three-dimensional world, intermodal perception, and so on, develops later in infancy than the Gibsons envision.

The longitudinal research of Daphne Maurer and her colleagues (Maurer, 2016, 2021; Maurer & Lewis, 2013) has focused on infants born with cataracts—a thickening of the lens of the eye that causes vision to become cloudy, opaque, and distorted and thus severely restricts infants' ability to experience their visual world. In studying infants whose cataracts were removed at different points in development, they discovered that those whose cataracts were

What roles do nature and nurture play in the infant's perceptual development?
lostinbids/E+/Getty Images

removed and new lenses placed in their eyes in the first several months after birth showed a normal pattern of visual development. However, the longer the delay in removing the cataracts, the more their visual development was impaired. In their research, Maurer and her colleagues (2007) have found that experiencing patterned visual input early in infancy is important for holistic and detailed face processing after infancy. Maurer's research program illustrates how deprivation and experience influence visual development, identifying an early sensitive period in which visual input is necessary for normal visual development (Maurer, 2021).

Today, it is clear that just as an extreme nativist position on perceptual development is unwarranted, an extreme empiricist position also is unwarranted. Much of very early perception develops from innate (nature) foundations, and the basic foundation of many perceptual abilities can be detected in newborns (Bornstein, Arterberry, & Mash, 2015). However, as infants develop, environmental experiences (nurture) refine or calibrate many perceptual functions, and they may be the driving force behind some functions (Amso & Johnson, 2010). The accumulation of experience with and knowledge about their perceptual world contributes to infants' ability to process coherent perceptions of people and things (Johnson, 2020a, b). Thus, a full portrait of perceptual development includes the influence of nature, nurture, and a developing sensitivity to information (Maurer, 2021).

3 Perceptual-Motor Coupling

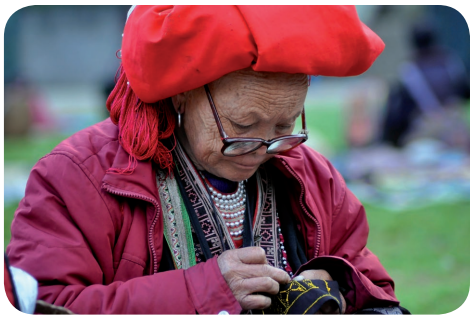
LG3 Discuss the connection between perception and action.

The infant is by no means as helpless at it looks and is quite capable of some very complex and important actions.

–Herb Pick
Developmental Psychologist, University of Minnesota

As we come to the end of this chapter, we return to the important theme of perceptual-motor coupling. The distinction between perceiving and doing has been a time-honored tradition in psychology. However, a number of experts on perceptual and motor development question whether this distinction makes sense (Adolph & Hoch, 2021). The main thrust of research in Esther Thelen's dynamic systems approach is to explore how people assemble motor behaviors for perceiving and acting. The main theme of the ecological approach of Eleanor and James J. Gibson is to discover how perception guides action. Action can guide perception, and perception can guide action. Only by moving one's eyes, head, hands, and arms and by moving from one location to another can an individual fully experience his or her environment and learn how to adapt to it. Perception and action are coupled.

Babies, for example, continually coordinate their movements with perceptual information to learn how to maintain balance, reach for objects in space, and move across various surfaces and terrains (Rachwani, Hoch, & Adolph, 2021). They are motivated to move by what they perceive. Consider the sight of an attractive toy across the room. In this situation, infants must perceive the current state of their bodies and learn how to use their limbs to reach the toy.



Perception and action are coupled throughout the human life span.
(*Left*): Anthony Cain/Flickr/Getty Images; (*right*): Salajean/Shutterstock

Although their movements at first are awkward and uncoordinated, babies soon learn to select patterns that are appropriate for reaching their goals.

Equally important is the other part of the perception-action coupling. That is, action educates perception (Rachwani, Hoch, & Adolph, 2021). For example, watching an object while exploring it manually helps infants to discriminate its texture, size, and hardness. Locomoting in the environment teaches babies about how objects and people look from different perspectives, or whether surfaces will support their weight. Individuals perceive in order to move and move in order to perceive. Perceptual and motor development do not occur in isolation from each other but instead are coupled.

How do infants develop new perceptual-motor couplings? Recall from our discussion earlier in this chapter that in the traditional view of Gesell, infants' perceptual-motor development is prescribed by a genetic plan to follow a fixed and sequential progression of stages in development. The genetic determination view has been replaced by the dynamic systems view that infants learn new perceptual-motor couplings by assembling skills for perceiving and acting. New perceptual-motor coupling is not passively accomplished; rather, the infant actively develops a skill to achieve a goal within the constraints set by the infant's body and the environment (Maurer, 2021).

Driving a car illustrates the coupling of perceptual and motor skills. The decline in perceptual-motor skills in late adulthood makes driving difficult for many older adults (Kim & others, 2020). Drivers over the age of 65 are involved in more traffic accidents than middle-aged adults because of mistakes such as improper turns, not yielding the right of way, and not obeying traffic signs; their younger counterparts are more likely to have accidents because they are speeding (Lavalliere & others, 2011). Older adults can compensate for declines in perceptual-motor skills by driving shorter distances, choosing less congested routes, and driving only in daylight.

Cognitive training programs have shown some success in older adults, including improving their driving safety and making driving less difficult. In one study conducted by Karlene Ball and her colleagues (2010), training designed to enhance speed of processing produced more than a 40 percent reduction in at-fault crashes over a six-year period.

Motor, Sensory, and Perceptual Development

1 Motor Development

LG1 Describe how motor skills develop.

The Dynamic Systems View

- Thelen's dynamic systems theory seeks to explain how motor behaviors are assembled by infants for perceiving and acting. Perception and action are coupled. According to this theory, motor skills are the result of many converging factors, such as the development of the nervous system, the body's physical properties and its movement possibilities, the goal the child is motivated to reach, and environmental support for the skill.
- In the dynamic systems view, motor development involves far greater complexity than the unfolding of a genetic blueprint.

Reflexes

- Reflexes govern the newborn's movements. They include the sucking, rooting, and Moro reflexes.

Gross Motor Skills

- Gross motor skills involve large-muscle activities. Key skills developed during infancy include control of posture and walking. Gross motor skills improve dramatically during childhood.
- Peak levels of physical performance often occur between 19 and 26 years of age. In general, older adults show a slowing of movement.

Fine Motor Skills

- Fine motor skills involve finely tuned motor actions. The onset of reaching and grasping marks a significant accomplishment. Fine motor skills continue to develop during childhood and then decline somewhat with aging.

2 Sensory and Perceptual Development

LG2 Outline the course of sensory and perceptual development.

What Are Sensation and Perception?

- Sensation occurs when information interacts with sensory receptors. Perception is the interpretation of sensation.

The Ecological View

- Created by the Gibsons, the ecological view states that people directly perceive information that exists in the world. Perception brings people in contact with the environment so that they can interact with and adapt to it.
- Affordances provide opportunities for interaction offered by objects that fit within our capabilities to perform activities.
- Researchers have developed a number of methods to assess the infant's perception, including the visual preference method (which Fantz used to determine young infants' interest in looking at patterned over nonpatterned displays), habituation and dishabituation, and tracking.

Visual Perception

- The infant's visual acuity increases dramatically during the first year of life. Infants can distinguish some colors by 8 weeks of age and possibly as early as 4 weeks. Young infants systematically scan human faces. By 3 months of age, infants show size and shape constancy.
- As visual perception develops, infants develop visual expectations. In Gibson and Walk's classic study, infants as young as 6 months of age had depth perception. Much of vision develops from biological foundations, but environmental experiences can contribute to the development of visual perception. During the preschool years, children become better at differentiating colors and scanning the visual world.
- After the early adult years, visual acuity declines. Eye accommodation decreases the most from 40 to 59 years of age. In older adults, the yellowing of the eye's lens reduces color differentiation, and the ability to see the periphery of a visual field declines. Significant declines

in visual functioning related to glare characterize adults 75 years and older and are even more severe among those who are 85 years and older. Three diseases that can impair the vision of older adults are cataracts, glaucoma, and macular degeneration.

Hearing

- The fetus can hear sounds such as the mother's voice and music during the last two months of pregnancy. Immediately after birth newborns can hear, but their sensory threshold is higher than that of adults. Developmental changes in the perception of loudness, pitch, and localization of sound occur during infancy.
- Hearing can start to decline by the age of 40, especially sensitivity to high-pitched sounds. However, hearing impairment usually doesn't become much of an impediment until late adulthood. Hearing aids can diminish hearing problems for many older adults.

Other Senses

- Newborns can respond to touch and feel pain. Sensitivity to pain decreases in late adulthood. Newborns can differentiate odors, and sensitivity to taste is present before birth. Smell and taste may decline in late adulthood, although in healthy individuals the decline is minimal.

Intermodal Perception

- Crude, exploratory forms of intermodal perception—the ability to relate and integrate information from two or more sensory modalities—are present in newborns and become sharper over the first year of life.

Nature/Nurture and Perceptual Development

- In theorizing about perception, nature advocates are referred to as nativists and nurture proponents are called empiricists. The Gibsons' ecological view that has guided much of perceptual development research leans toward a nativist approach but still allows for developmental changes in distinctive features. Piaget's constructivist view leans toward an empiricist approach, emphasizing that many perceptual accomplishments must await the development of cognitive stages in infancy. A strong empiricist approach is unwarranted. A full account of perceptual development acknowledges the roles of nature, nurture, and the developing sensitivity to information.

3 Perceptual-Motor Coupling

LG3 Discuss the connection between perception and action.

- Perception and action often are not isolated but rather are coupled. Action can guide perception and perception can guide action. Individuals perceive in order to move and move in order to perceive.

preview

Cognitive developmental approaches place a special emphasis on how individuals actively construct their thinking. They also focus heavily on how thinking changes from one point in development to another. In this chapter, we will focus on the cognitive developmental approaches of Jean Piaget and Lev Vygotsky. We also will explore the possibility that adults think in a qualitatively more advanced way than adolescents do.

1 Piaget's Theory of Cognitive Development

schemes In Piaget's theory, actions or mental representations that organize knowledge.

assimilation Piagetian concept in which children use existing schemes to incorporate new information.

accommodation Piagetian concept of incorporating new experiences into existing schemes.

Poet Nora Perry asks, "Who knows the thoughts of a child?" As much as anyone, Piaget knew. Through careful observations of his own three children—Laurent, Lucienne, and Jacqueline—and observations of and interviews with other children, Piaget reached groundbreaking conclusions regarding the ways children think about the world.

Piaget's theory is a general, unifying story of how biology and experience sculpt cognitive development. Piaget thought that, just as our physical bodies have structures that enable us to adapt to the world, we build mental structures that help us adapt to the world. Adaptation involves adjusting to new environmental demands. Piaget stressed that children actively construct their own cognitive worlds; information is not just poured into their minds from the environment. He sought to discover how children at different points in their development think about the world and how systematic changes in their thinking occur.

PROCESSES OF DEVELOPMENT

What processes do children use as they construct their knowledge of the world? Piaget developed several concepts to answer this question; especially important among them are schemes, assimilation, accommodation, organization, equilibrium, and equilibration.

Schemes As the infant or child seeks to construct an understanding of the world, said Piaget (1954), the developing brain creates **schemes.** These are actions or mental representations that organize knowledge. In Piaget's theory, behavioral schemes (physical activities) characterize infancy and mental schemes (cognitive activities) develop in childhood (Lamb, Bornstein, & Teti, 2002). A baby's schemes are structured by simple actions that can be performed on objects, such as sucking, looking, and grasping. Older children have schemes that include strategies and plans for solving problems. By the time we reach adulthood, we have constructed an enormous number of diverse schemes, ranging from driving a car to balancing a budget to the concept of fairness.

Next, we will look at other important cognitive processes—assimilation, accommodation, organization, and equilibration—that individuals use throughout the life span in actively constructing their knowledge.

Assimilation and Accommodation To explain how children use and adapt their schemes, Piaget offered two concepts: assimilation and accommodation. **Assimilation** occurs when children incorporate new experiences into existing schemes.

Think about a toddler who has learned to use the word *car* to identify the family's blue car. The toddler might then see other different colors and brands of cars and call them "cars," thus assimilating these vehicles into his or her existing scheme. **Accommodation** occurs when

children adjust their schemes to account for new information and experiences. For example, the child soon learns that other moving vehicles, such as motorcycles and trucks, are not cars and fine-tunes the category to exclude motorcycles and trucks, accommodating the scheme.

Assimilation and accommodation operate even in very young infants. Newborns reflexively suck everything that touches their lips; they assimilate all sorts of objects into their sucking scheme. By sucking different objects, they learn about their taste, texture, shape, and so on. After several months of experience, though, they construct their understanding of the world differently. Some objects, such as fingers and the mother's breast, can be sucked, and others, such as fuzzy blankets, should not be sucked. In other words, they accommodate their sucking scheme.

Organization To make sense of their world, said Piaget, children cognitively organize their experiences. **Organization** in Piaget's theory is the grouping of isolated behaviors and thoughts into a higher-order system. Continual refinement of this organization is an inherent part of development. A child who has only a vague idea about how to use a hammer may also have a vague idea about how to use other tools. After learning how to use each one, the child relates these uses, organizing his knowledge.

Equilibration and Stages of Development Assimilation and accommodation always take the child to a higher ground, according to Piaget. In trying to understand the world, the child inevitably experiences cognitive conflict, or *disequilibrium*. That is, the child constantly encounters inconsistencies and counterexamples to his or her existing schemes. For example, if a child believes that pouring water from a short and wide container into a tall and narrow container changes the amount of water, then the child might be puzzled by where the "extra" water came from and whether there is actually more water to drink. The puzzle creates disequilibrium; for Piaget, an internal search for equilibrium creates motivation for change. The child assimilates and accommodates, adjusting old schemes, developing new schemes, and organizing and reorganizing the old and new schemes. Eventually, the organization is fundamentally different from the old organization; it is a new way of thinking.

In short, according to Piaget, children constantly assimilate and accommodate as they seek equilibrium. There is considerable movement between states of cognitive equilibrium and disequilibrium as assimilation and accommodation work in concert to produce cognitive change. **Equilibration** is the name Piaget gave to this mechanism by which children shift from one stage of thought to the next.

The result of these processes, according to Piaget, is that individuals go through four stages of development. A different way of understanding the world makes each stage more advanced than the previous one. Cognition is *qualitatively* different in one stage compared with another. In other words, the way children reason at one stage is different from the way they reason at another stage. Figure 1 provides a brief description of the four Piagetian stages.

In Piaget's view, what is a scheme? What schemes might this young infant be displaying?
Maya Kovacheva Photography/iStockphoto/Getty Images

SENSORIMOTOR STAGE

The **sensorimotor stage** lasts from birth to about 2 years of age. In this stage, infants construct an understanding of the world by coordinating sensory experiences (such as seeing and hearing) with physical, motoric actions–hence the term "sensorimotor." At the beginning of this stage, newborns have little more than reflexes with which to work. By the end of the sensorimotor stage, 2-year-olds can produce complex sensorimotor patterns and use primitive symbols.

Substages Piaget divided the sensorimotor stage into six substages: (1) simple reflexes; (2) first habits and primary circular reactions; (3) secondary circular reactions; (4) coordination of secondary circular reactions; (5) tertiary circular reactions, novelty, and curiosity; and (6) internalization of schemes. Piaget argued that each substage builds on the previous one.

Simple reflexes, the first sensorimotor substage, corresponds to the first month after birth. In this substage, sensation and action are coordinated primarily through reflexive behaviors such as rooting and sucking. Soon the infant produces behaviors that resemble reflexes in the absence of the usual stimulus for the reflex. For example, a newborn will suck a nipple or bottle only when it is placed directly in the baby's mouth or touched to the lips. But soon the infant might suck when a bottle or nipple is only nearby. Even in the first month of life, the infant is initiating action and actively structuring experiences.

organization Piagetian concept of grouping isolated behaviors and thoughts into a higher-order, more smoothly functioning cognitive system.

equilibration A mechanism that Piaget proposed to explain how children shift from one stage of thought to the next.

sensorimotor stage The first of Piaget's stages, which lasts from birth to about 2 years of age, during which infants construct an understanding of the world by coordinating sensory experiences (such as seeing and hearing) with physical, motoric actions.

Sensorimotor Stage

The infant constructs an understanding of the world by coordinating sensory experiences with physical actions. An infant progresses from reflexive, instinctual action at birth to the beginning of symbolic thought toward the end of the stage.

Birth to 2 Years of Age

Preoperational Stage

The child begins to represent the world with words and images. These words and images reflect increased symbolic thinking and go beyond the connection of sensory information and physical action.

2 to 7 Years of Age

Concrete Operational Stage

The child can now reason logically about concrete events and classify objects into different sets.

7 to 11 Years of Age

Formal Operational Stage

The adolescent reasons in more abstract, idealistic, and logical ways.

11 Years of Age Through Adulthood

FIGURE **1**

PIAGET'S FOUR STAGES OF COGNITIVE DEVELOPMENT.

I wish I could travel by the road that crosses the baby's mind, and out beyond all bounds; where messengers run errands for no cause between the kingdoms of kings of no history; where reason makes kites of her laws and flies them, and truth sets facts free from its fetters.

—Rabindranath Tagore

Bengali Poet and Essayist, 20th Century

Primary circular reactions is the second sensorimotor substage, which develops between 1 and 4 months of age. A *primary circular reaction* is a scheme based on the attempt to reproduce an event that initially occurred by chance. For example, suppose an infant accidentally sucks his fingers when they are placed near his mouth. Later, he searches for his fingers to suck them again, but the fingers do not cooperate because the infant cannot coordinate visual and manual actions.

Habits and circular reactions are stereotyped—that is, the infant repeats them the same way each time. During this substage, the infant's own body remains the infant's center of attention. There is no outward pull by environmental events.

Secondary circular reactions is the third sensorimotor substage, which develops between 4 and 8 months of age. In this substage, the infant becomes more object oriented, moving beyond preoccupation with the self. The infant's schemes are not intentional or goal-directed, but they are repeated because of their consequences. By chance, an infant might shake a rattle. The infant repeats this action for the sake of its fascination. This is a *secondary circular reaction:* an action repeated because of its consequences. The infant also imitates some simple actions, such as the baby talk or burbling of adults, and some physical gestures. However, the baby imitates only actions that she is already able to produce.

Coordination of secondary circular reactions is Piaget's fourth sensorimotor substage, which develops between 8 and 12 months of age. To progress into this substage, the infant must coordinate vision and touch, hand and eye. Actions become more outwardly directed. Significant changes during this substage involve the coordination of schemes and intentionality. Infants readily combine and recombine previously learned schemes in a coordinated way. They might look at an object and grasp it simultaneously, or they might visually inspect a toy, such as a rattle, and finger it simultaneously, exploring it tactilely. Actions are even more outwardly directed than before. Related to this coordination is the second achievement—the presence of intentionality. For example, infants might manipulate a stick in order to bring a desired toy within reach, or they might knock over one block to reach and play with another one.

Tertiary circular reactions, novelty, and curiosity is Piaget's fifth sensorimotor substage, which develops between 12 and 18 months of age. In this substage, infants become intrigued

by the many properties of objects and by the many things that they can make happen to objects. A block can be made to fall, spin, hit another object, and slide across the ground. *Tertiary circular reactions* are schemes in which the infant purposely explores new possibilities with objects, continually doing new things to them and exploring the results. Piaget says that this stage marks the starting point for human curiosity and interest in novelty.

Internalization of schemes is Piaget's sixth and final sensorimotor substage, which develops between 18 and 24 months of age. In this substage, the infant develops the ability to use primitive symbols. For Piaget, a symbol is an internalized sensory image or word that represents an event. Primitive symbols permit the infant to think about concrete events without directly acting them out or perceiving them. Moreover, symbols allow the infant to manipulate and transform the represented events in simple ways. In a favorite Piagetian example, Piaget's young daughter saw a matchbox being opened and closed. Later, she mimicked the event by opening and closing her mouth. This was an obvious expression of her image of the event. A summary of Piaget's six substages of sensorimotor development is shown in Figure 2.

Object Permanence Imagine how chaotic and unpredictable your life would be if you could not distinguish between yourself and your world. This is what the life of a newborn must be like, according to Piaget. There is no differentiation between the self and world; objects have no separate, permanent existence.

By the end of the sensorimotor period, objects are both separate from the self and permanent. **Object permanence** is the understanding that objects continue to exist even when they cannot be seen, heard, or touched. Acquiring the sense of object permanence is one of the infant's most important accomplishments, according to Piaget.

How can anyone know whether an infant has a sense of object permanence? The principal way that object permanence is studied is by watching an infant's reaction when an interesting object disappears (see Figure 3). If infants search for the object, it is assumed that they believe it continues to exist.

Object permanence is just one of the basic concepts about the physical world developed by babies. To Piaget, children, even infants, are much like little scientists, examining the world to see how it works. How can the accuracy of this view of children's development be assessed? The *Connecting with Research* interlude describes some of the ways in which adult scientists try to discover what these "baby scientists" are finding out about the world.

This 17-month-old is in Piaget's stage of tertiary circular reactions. *What might the infant do to suggest that she is in this stage?*
Tom Grill/Corbis/Getty Images

object permanence The Piagetian term for one of an infant's most important accomplishments: understanding that objects continue to exist even when they cannot directly be seen, heard, or touched.

Substage	Age	Description	Example
1 Simple reflexes	Birth to 1 month	Coordination of sensation and action through reflexive behaviors.	Rooting, sucking, and grasping reflexes; newborns suck reflexively when their lips are touched.
2 Primary circular reactions	1 to 4 months	A scheme based on the attempt to reproduce an event that initially occurred by chance.	Repeating a body sensation first experienced by chance (sucking thumb, for example); then infants might accommodate actions by sucking their thumb differently from how they suck on a nipple.
3 Secondary circular reactions	4 to 8 months	Infants become more object-oriented, moving beyond self-preoccupation; they repeat actions that bring interesting or pleasurable results.	An infant coos to make a person stay near; as the person starts to leave, the infant coos again.
4 Coordination of secondary circular reactions	8 to 12 months	Coordination of vision and touch—hand-eye coordination; coordination of schemes and intentionality.	Infant manipulates a stick in order to bring an attractive toy within reach.
5 Tertiary circular reactions, novelty, and curiosity	12 to 18 months	Infants become intrigued by the many properties of objects and by the many things they can make happen to objects; they experiment with new behavior.	A block can be made to fall, spin, hit another object, and slide across the ground.
6 Internalization of schemes	18 to 24 months	Infants develop the ability to use primitive symbols and form enduring mental representations.	An infant who has never thrown a temper tantrum before sees a playmate throw a tantrum; the infant retains a memory of the event, then throws one himself the next day.

FIGURE **2**

PIAGET'S SIX SUBSTAGES OF SENSORIMOTOR DEVELOPMENT.

FIGURE 3

OBJECT PERMANENCE. Piaget argued that object permanence is one of infancy's landmark cognitive accomplishments. For this 5-month-old boy, "out of sight" is literally out of mind. The infant looks at the toy dog (*left*), but when his view of the toy is blocked (*right*), he does not search for it. Several months later, he will search for the hidden toy dog, an action reflecting the presence of object permanence.

connecting with research

How Do Researchers Study Infants' Understanding of Object Permanence and Causality?

Courtesy Renée Baillargeon

Renée Baillargeon
Key Points:

- infants' understanding of object permanence
- infants' understanding of causality
- infants' perception of violated expectations

Two accomplishments of infants that Piaget examined were the development of object permanence and the child's understanding of causality. Let's examine two research studies that address these topics.

In both studies, Renée Baillargeon and her colleagues used a research method that involves violation of expectations (Scott, Roby, & Baillargeon, 2021). In this method, infants see an event happen as it normally would. Then the event is changed, often in a way that creates a physically impossible event. If infants look longer at the changed event, their reaction indicates they are surprised by it. In other words, this reaction is interpreted to indicate that the infant had certain expectations about the world that were violated.

In one study that focused on object permanence, researchers showed infants a toy car that moved down an inclined track, disappeared behind a screen, and then reemerged at the other end, still on the track (Baillargeon & DeVos, 1991). After this sequence was repeated several times, something different occurred: A toy mouse was placed behind the track but was hidden by the screen while the car rolled by. This was the "possible" event. Then, the researchers created an "impossible event": The toy mouse was placed on the track but was secretly removed after the screen was lowered so that the car seemed to go through the mouse. In this study, infants as young as 3½ months of age looked longer at the impossible event than at the possible event, an indication that they were surprised by it. Their surprise suggested that they remembered not only that the toy mouse still existed (object permanence) but where it was located.

Another study focused on the infant's understanding of causality (Kotovsky & Baillargeon, 1994). In this research, a cylinder rolls down a ramp and hits a toy bug at the bottom of the ramp. By 5½ to 6½ months of age, after infants have seen how far the bug will be pushed by a medium-sized cylinder, their reactions indicate that they understand that the bug will roll farther if it is hit by a large cylinder than if it is hit by a small cylinder. Thus, by the middle of the first year of life, these infants understood that the size of a moving object determines how far it will move a stationary object that it collides with.

In Baillargeon's (2008, 2014; Baillargeon & others, 2012) view, infants have a pre-adapted, innate bias called the principle of persistence that explains their assumption that objects don't change their properties—including how solid they are, their location, their color, and their form—unless some external factor intervenes (a person moves the object, for example). Shortly, we will revisit the extent to which nature and nurture are at work in the changes that take place in the infant's cognitive development.

Research discussed in this interlude and elsewhere indicates that infants develop object permanence earlier than Piaget proposed (Baillargeon, 2014, 2016). Indeed, as you will see in the next section, a major theme of infant cognitive development today is that infants are more cognitively competent than Piaget envisioned. What methods might researchers use to arrive at this conclusion?

Evaluating Piaget's Sensorimotor Stage Piaget opened up a new way of looking at infants with his view that their main task is to coordinate their sensory impressions with their motor activity. However, the infant's cognitive world is not as neatly packaged as Piaget portrayed it, and some of Piaget's explanations for the causes of change are debated. In the past several decades, sophisticated experimental techniques have been devised to study infants, and there have been a large number of research studies on infant development. Much of the new research suggests that Piaget's view of sensorimotor development needs to be modified (Adolph & Hoch, 2021; Hayne & Herbert, 2021; Oakes, 2021).

The A-Not-B Error One modification concerns Piaget's claim that certain processes are crucial in transitions from one stage to the next. The data do not always support his explanations. For example, in Piaget's theory, an important feature in the progression into substage 4, *coordination of secondary circular reactions*, is an infant's inclination to search for a hidden object in a familiar location rather than to look for the object in a new location. For example, if a toy is hidden twice, initially at location A and subsequently at location B, 8- to 12-month-old infants search initially and correctly at location A. But when the toy is subsequently hidden at location B while the infants watch, they make the mistake of continuing to search for it at location A. **A-not-B error** is the term used to describe this common mistake. Older infants are less likely to make the A-not-B error because their concept of object permanence is more complete. Researchers have found, however, that the A-not-B error does not show up consistently (MacNeill & others, 2018; Sophian, 1985). The evidence indicates that A-not-B errors are sensitive to the delay between hiding the object at B and the infant's attempt to find it (Diamond, 1985). Thus, the A-not-B error might be due to a failure in memory. And A-not-B performance may be linked to attention as well. For example, in one study, 5-month-olds' more focused attention on a separate task involving a puppet was linked to better performance on an A-not-B task that involved locating an object after it was hidden from view (Marcovitch & others, 2016). Another explanation for A-not-B error is that infants tend to repeat a previous motor behavior (Clearfield & others, 2006). And in longitudinal research, attention at 5 months was related to A-not-B performance at 10 months, and also to executive function in early childhood and reading competence at 6 years of age (Blankenship & others, 2019).

Perceptual Development and Expectations A number of theorists, such as Eleanor Gibson (2001) and Elizabeth Spelke (2017), argue that infants' perceptual abilities are highly developed very early in life. Spelke argues that young infants interpret the world as having predictable occurrences. For example, in the chapter on "Motor, Sensory, and Perceptual Development," you read about research that demonstrated the presence of intermodal perception—the ability to coordinate information from two or more sensory modalities, such as vision and hearing—by 3½ months of age, much earlier than Piaget would have predicted (Spelke & Owsley, 1979).

Research also suggests that infants develop the ability to understand how the world works at a very early age (Lin, Stavans, & Baillargeon, 2021; Newcombe, 2021; Oakes, 2021). For example, researchers have explored what kinds of expectations infants form. Are infants born expecting the world to obey basic physical laws, such as gravity, or if not, then when do they learn about how the world works? Experiments by Elizabeth Spelke (2011, 2016, 2017) have addressed these questions. She placed babies in front of a puppet stage and showed them a series of actions that are unexpected if you know how the physical world works—for example, one ball seemed to roll through a solid barrier, another seemed to leap between two platforms, and a third appeared to hang in midair (Spelke, 1979). Spelke measured and compared the babies' looking times for unexpected and expected actions. She concluded that by 4 months of age, even though infants do not yet have the ability to talk about objects, move around objects, manipulate objects, or even see objects with high resolution, they expect objects to be solid and continuous. However, at 4 months of age, infants do not expect an object to obey gravitational constraints (Spelke & others, 1992). Similarly, research by Renee Baillargeon (2014, 2016) documents that infants as young as 3 to 4 months expect objects to be *substantial* (in the sense that other objects cannot move through them) and *permanent* (in the sense that objects continue to exist when they are hidden).

In sum, researchers such as Baillargeon and Spelke conclude that infants see objects as bounded, unitary, solid, and separate from their background at a very young age, possibly at

developmental **connection**

A-not-B error This error occurs when infants make the mistake of selecting the familiar hiding place (A) of an object rather than its new hiding place (B) as they progress into substage 4 in Piaget's sensorimotor stage.

According to contemporary researchers, what revisions in Piaget's theory of sensorimotor development need to be made?
David Kenny/Getty Images

birth or shortly thereafter, but definitely by 3 to 4 months of age—much earlier than Piaget envisioned. Young infants still have much to learn about objects, but the world appears both stable and orderly to them.

However, some critics argue that the experiments conducted by Baillargeon and Spelke mainly demonstrate perceptual competencies or detection of regularities in the environment (Heyes, 2014; Ruffman, 2014). The critics stress that the infants' responses in their studies reflect a very rudimentary understanding that likely differs greatly from the understanding of older children.

The Nature-Nurture Issue In considering the big issue of whether nature or nurture plays the more important role in infant development, Elizabeth Spelke (2017) comes down clearly on the side of nature. Spelke endorses a **core knowledge approach,** which states that infants are born with domain-specific innate knowledge systems. Among these domain-specific knowledge systems are those involving space, number sense, object permanence, and language. Strongly influenced by evolution, the core knowledge domains are theorized to be prewired to allow infants to make sense of their world (Coubart & others, 2014). After all, Spelke concludes, how could infants possibly grasp the complex world in which they live if they didn't come into the world equipped with core sets of knowledge? In this approach, the innate core knowledge domains form a foundation around which more mature cognitive functioning and learning develop. The core knowledge approach argues that Piaget greatly underestimated the cognitive abilities of infants, especially young infants (Spelke, 2017).

Recently, researchers also have explored whether preverbal infants might have a built-in innate sense of morality (Buyukozer Dawkins & others, 2021; Scott, Roby, & Baillargeon, 2021). In this research, infants as young as 4 months of age are more likely to make visually guided reaches toward a puppet who has acted as a helper (such as helping someone get up a hill, assisting in opening a box, or giving a ball back) rather than toward a puppet who has hindered others' efforts to achieve such goals (Hamlin, 2013a, b, 2014; Hamlin & Sitch, 2021).

In criticizing the core knowledge approach, British developmental psychologist Mark Johnson (2008) says that the infants Spelke assesses in her research already have accumulated hundreds, and in some cases even thousands, of hours of experience in grasping what the world is about, which gives considerable room for the environment's role in the development of infant cognition (Highfield, 2008). According to Johnson (2008), infants likely come into the world with "soft biases to perceive and attend to different aspects of the environment, and to learn about the world in particular ways." In line with Johnson's view, one major criticism is that nativists completely neglect the infant's social immersion in the world and instead focus only on what happens inside the infant's head apart from the environment (Nelson, 2013). And recently, the view that the emergence of morality in infancy is innate was described as problematic (Carpendale & Hammond, 2016). Instead, it was argued that morality may emerge through infants' early interaction with others and later transformation through language and reflective thought. And as discussed in the chapter "Biological Beginnings," another major criticism is that the modularity of the mind view does not adequately recognize the extensive connectivity of various regions of the brain.

Although debate about the cause and course of infant cognitive development continues, most developmentalists today agree that Piaget underestimated the early cognitive accomplishments of infants and that both nature and nurture are involved in infants' cognitive development (Bell & Broomell, 2021; Rachwani, Hoch, & Adolph, 2021).

Conclusions In sum, many researchers conclude that Piaget wasn't specific enough about how infants learn about their world and that infants, especially young infants, are more competent than Piaget thought (Hespos & Anderson, 2021). As researchers have examined the specific ways that infants learn, the field of infant cognition has become very specialized. There are many researchers working on different questions, with no general theory emerging that can connect all of the different findings. Their theories often are local theories, focused on specific research questions, rather than grand theories like Piaget's (Kuhn, 1998). Among the unifying themes in the study of infant cognition are seeking to understand more precisely how developmental changes in cognition take place, to answer questions about the relative importance of nature and nurture, and to examine the brain's role in cognitive development (Amso & Tummeltshammer, 2021; Richards & Conte, 2021). Exploring connections between brain, cognition, and development is a central focus in the recently emerging field of *developmental cognitive neuroscience*.

core knowledge approach Theory that infants are born with domain-specific innate knowledge systems. Among these domain-specific knowledge systems are those involving space, number sense, object permanence, and language.

PREOPERATIONAL STAGE

The cognitive world of the preschool child is creative, free, and fanciful. The imaginations of preschool children work overtime, and their mental grasp of the world improves. Piaget described the preschool child's cognition as preoperational. What did he mean?

The **preoperational stage,** which lasts from approximately 2 to 7 years of age, is the second Piagetian stage. In this stage, children begin to represent the world with words, images, and drawings. They form stable concepts and begin to reason. At the same time, the young child's cognitive world is dominated by egocentrism and magical beliefs.

Because Piaget called this stage "preoperational," it might sound like an unimportant waiting period. Not so. However, the label *preoperational* emphasizes that the child does not yet perform **operations,** which are reversible mental actions that allow children to do mentally what they previously could do only physically. Mentally adding and subtracting numbers are examples of operations. *Preoperational thought* is the beginning of the ability to reconstruct in thought what has been established in behavior. It can be divided into two substages: the symbolic function substage and the intuitive thought substage.

The Symbolic Function Substage

The **symbolic function substage** is the first substage of preoperational thought, occurring roughly between the ages of 2 and 4. In this substage, the young child gains the ability to mentally represent an object that is not present. This ability vastly expands the child's mental world (Callaghan & Corbit, 2015). Young children use scribble designs to represent people, houses, cars, clouds, and so on; they begin to use language and engage in pretend play. However, although young children make distinct progress during this substage, their thinking still has important limitations, two of which are egocentrism and animism.

Egocentrism is the inability to distinguish between one's own perspective and someone else's perspective. Piaget and Barbel Inhelder (1969) initially studied young children's egocentrism by devising the three mountains task (see Figure 4). The child walks around the model of the mountains and becomes familiar with what the mountains look like from different perspectives and can see that there are different objects on the mountains. The child is then seated on one side of the table on which the mountains are placed. The experimenter moves a doll to different locations around the table, at each location asking the child to select from a series of photos the one photo that most accurately reflects the view that the doll is seeing. Children in the preoperational stage often pick their own view rather than the doll's view. Preschool children frequently show the ability to take another's perspective on some tasks but not others.

Animism, another limitation of preoperational thought, is the belief that inanimate objects have lifelike qualities and are capable of action (Gelman & Opfer, 2004). A young child might show animism by saying, "That tree pushed the leaf off, and it fell down" or "The sidewalk made me mad; it made me fall down." A young child who uses animism fails to distinguish the appropriate occasions for using human and nonhuman perspectives (Opfer & Gelman, 2011).

preoperational stage The second Piagetian developmental stage, which lasts from about 2 to 7 years of age; children begin to represent the world with words, images, and drawings.

operations Reversible mental actions that allow children to do mentally what before they had done only physically.

egocentrism The inability to distinguish between one's own and someone else's perspective; an important feature of preoperational thought.

animism A facet of preoperational thought—the belief that inanimate objects have lifelike qualities and are capable of action.

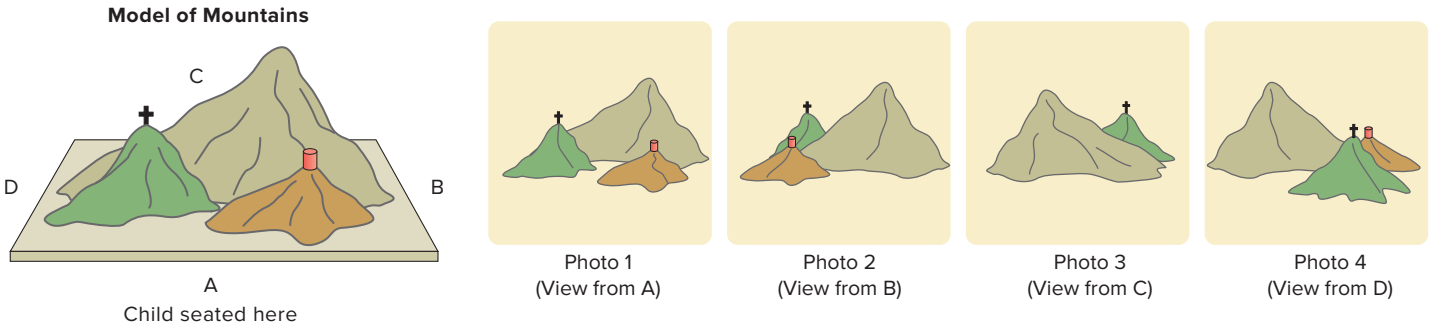

FIGURE **4**

THE THREE MOUNTAINS TASK. Photo 1 shows the child's perspective from where he or she is sitting. Photos 2, 3, and 4 were taken from different perspectives. For example, Photo 2 shows what the mountains look like to a person sitting at spot B. When asked what a view of the mountains looks like from spot B, the child selects Photo 1, taken from spot A (the child's own view at the time) instead of Photo 2, the correct view.

FIGURE **5**

THE SYMBOLIC DRAWINGS OF YOUNG CHILDREN. (*a*) A 3½-year-old's symbolic drawing. Halfway into his drawing, the 3½-year-old artist said it was a "pelican kissing a seal." (*b*) This 11-year-old's drawing is neater and more realistic but also less inventive.

Wolf, D., and Nove, J. "The Symbolic Drawings of Young Children," Courtesy of D. Wolf and J. Nove. Copyright Dennie Palmer Wolf, Annenberg Institute, Brown University. All rights reserved. Used with permission.

Possibly because young children are not very concerned about reality, their drawings are fanciful and inventive. Suns are blue, skies are yellow, and cars float on clouds in their symbolic, imaginative world. One 3½-year-old looked at a scribble he had just drawn and described it as a pelican kissing a seal (see Figure 5a). The symbolism is simple but strong, like abstractions found in some modern art. Twentieth-century Spanish artist Pablo Picasso commented, "I used to draw like Raphael but it has taken me a lifetime to draw like young children." In the elementary school years, a child's drawings become more realistic, neat, and precise (see Figure 5b). Suns are yellow, skies are blue, and cars travel on roads (Winner, 1986).

The Intuitive Thought Substage

The **intuitive thought substage** is the second substage of preoperational thought, occurring between approximately 4 and 7 years of age. In this substage, children begin to use primitive reasoning and want to know the answers to all sorts of questions. Consider 4-year-old Tommy, who is at the beginning of the intuitive thought substage. Although he is starting to develop his own ideas about the world he lives in, his ideas are still simple, and he is not very good at thinking things out. He has difficulty understanding events that he knows are taking place but that he cannot see. His fantasized thoughts bear little resemblance to reality. He cannot yet answer the question "What if?" in any reliable way. For example, he has only a vague idea of what would happen if a car were to hit him. He also has difficulty negotiating traffic because he cannot do the mental calculations necessary to estimate whether an approaching car will hit him when he crosses the road.

By the age of 5, children have just about exhausted the adults around them with "why" questions. The child's questions signal the emergence of interest in reasoning and in figuring out why things are the way they are. Following are some samples of the questions children ask during the questioning period of 4 to 6 years of age (Elkind, 1976):

What makes you grow up?
Who was the mother when everybody was a baby?
Why do leaves fall?
Why does the sun shine?

Piaget called this substage *intuitive* because young children seem so sure about their knowledge and understanding yet are unaware of how they know what they know. That is, they know something but know it without the use of rational thinking.

Centration and the Limits of Preoperational Thought

One limitation of preoperational thought is **centration,** a centering of attention on one characteristic to the exclusion of all others. Centration is most clearly evidenced in young children's lack of **conservation,** the awareness that altering an object's or a substance's appearance does not change its basic properties. For example, to adults, it is obvious that a certain amount of liquid stays the same, regardless of a container's shape. But this is not at all obvious to young children. Instead, they are struck by the height of the liquid in the container; they focus on that characteristic to the exclusion of others.

The situation that Piaget devised to study conservation is his most famous task. In the conservation task, children are presented with two identical beakers, each filled to the same level with liquid (see Figure 6). They are asked if these beakers have the same amount of liquid, and they usually say yes. Then the liquid from one beaker is poured into a third beaker, which is taller and thinner than the first two. The children are then asked if the amount of liquid in the tall, thin beaker is equal to that which remains in one of the original beakers. Children who are younger than 7 or 8 years old usually say no and justify their answers in terms of the differing height or width of the beakers. Older children usually answer yes and justify their answers appropriately ("If you poured the water back, the amount would still be the same").

In Piaget's theory, failing the conservation-of-liquid task is a sign that children are at the preoperational stage of cognitive development. The failure demonstrates not only centration but also an inability to mentally reverse actions. To understand this concept, see the conservation-of-matter example shown in Figure 7. In the row labeled "matter" you'll see that preoperational children say the longer shape has more clay because they assume that "longer is more." Preoperational children cannot mentally reverse the clay-rolling process to see that the amount of clay is the same in both the shorter ball shape and the longer stick shape.

conservation The awareness that altering the appearance of an object or a substance does not change its basic properties.

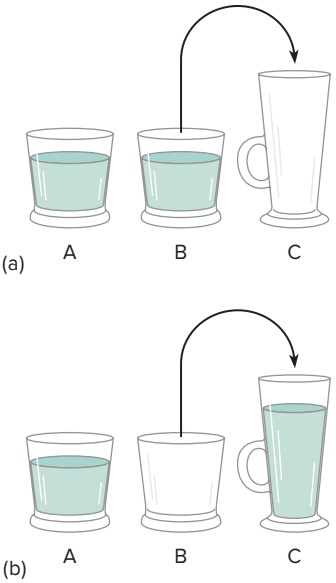

FIGURE 6

PIAGET'S CONSERVATION TASK. The beaker test is a well-known Piagetian test to determine whether a child can think operationally—that is, can mentally reverse actions and show conservation of the substance. (*a*) Two identical beakers are presented to the child. Then the experimenter pours the liquid from B into C, which is taller and thinner than A or B. (*b*) The child is asked if these beakers (A and C) have the same amount of liquid. The preoperational child says "no." When asked to point to the beaker that has more liquid, the preoperational child points to the tall, thin beaker.

Marmaduke St. John/Alamy Stock Photo

In Figure 7 you can see that, in addition to failing the conservation-of-liquid task, preoperational children also fail to conserve number, matter, and length. However, children often vary in their performance on different conservation tasks. Thus, a child might be able to conserve volume but not number. An fMRI brain-imaging study of conservation of number revealed that advances in a network in the parietal and frontal lobes were linked to 9- and 10-year-olds' conservation success in comparison with non-conserving 5- and 6-year-olds (Houde & others, 2011).

Type of Conservation	Initial Presentation	Manipulation	Preoperational Child's Answer
Number	 Two identical rows of objects are shown to the child, who agrees they have the same number.	 One row is lengthened and the child is asked whether one row now has more objects.	Yes, the longer row.
Matter	Two identical balls of clay are shown to the child. The child agrees that they are equal.	The experimenter changes the shape of one of the balls and asks the child whether they still contain equal amounts of clay.	No, the longer one has more.
Length	 Two sticks are aligned in front of the child. The child agrees that they are the same length.	 The experimenter moves one stick to the right, then asks the child if they are equal in length.	No, the one on the top is longer.

FIGURE 7

SOME DIMENSIONS OF CONSERVATION: NUMBER, MATTER, AND LENGTH. *What characteristics of preoperational thought do children demonstrate when they fail these conservation tasks?*

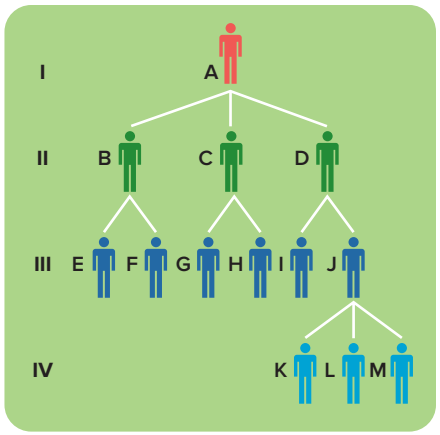

FIGURE **8**

CLASSIFICATION: AN IMPORTANT ABILITY IN CONCRETE OPERATIONAL THOUGHT. A family tree of four generations (*I to IV*): The preoperational child has trouble classifying the members of the four generations; the concrete operational child can classify the members vertically, horizontally, and obliquely (up and down and across). For example, the concrete operational child understands that a family member can be a son, a brother, and a father, all at the same time.

Some developmentalists do not believe Piaget was entirely correct in his estimate of when children's conservation skills emerge. For example, Rochel Gelman (1969) showed that when the child's attention to relevant aspects of the conservation task has improved, the child is more likely to conserve. Gelman has also demonstrated that attentional training on one dimension, such as number, improves the preschool child's performance on another dimension, such as mass. Thus, Gelman noted that conservation appears earlier than Piaget thought and that attention is especially important in explaining conservation.

CONCRETE OPERATIONAL STAGE

Piaget proposed that the **concrete operational stage** lasts from approximately 7 to 11 years of age. In this stage, children can perform concrete operations, and they can reason logically as long as reasoning can be applied to specific or concrete examples. Remember that *operations* are mental actions that are reversible, and *concrete operations* are operations that are applied to real, concrete objects. When a child adds two apples together with four apples and concludes that there are now six apples, she is performing a concrete operation.

The conservation tasks described earlier indicate whether children are capable of concrete operations. Concrete operations allow the child to consider several characteristics rather than to focus on a single property of an object. In the clay example, the preoperational child is likely to focus on height or width. The concrete operational child coordinates information about both dimensions.

What other abilities are characteristic of children who have reached the concrete operational stage? One important skill is the ability to classify or divide things into different sets or subsets and to consider their interrelationships. Consider the family tree of four generations that is shown in Figure 8 (Furth & Wachs, 1975). This family tree suggests that the grandfather (A) has three children (B, C, and D), each of whom has two children (E through J), and that one of these children (J) has three children (K, L, and M). A child who comprehends the classification system can move up and down a level, across a level, and up and down and across within the system. The concrete operational child understands that person J can at the same time be father, brother, and grandson, for example.

Children who have reached the concrete operational stage are also capable of **seriation,** which is the ability to order stimuli along a quantitative dimension (such as length). To see if students can serialize, a teacher might haphazardly place eight sticks of different lengths on a table. The teacher then asks the students to order the sticks by length. Many young children end up with two or three small groups of "big" sticks or "little" sticks, rather than a correct ordering of all eight sticks. Another mistaken strategy they use is to evenly line up the tops of the sticks but ignore the bottoms. The concrete operational thinker who is capable of seriation simultaneously understands that each stick must be longer than the one that precedes it and shorter than the one that follows it.

Another aspect of reasoning about the relations between classes is **transitivity,** which is the ability to logically combine relations to reach certain conclusions. In this case, consider three sticks (A, B, and C) of differing lengths. A is the longest, B is intermediate in length, and C is the shortest. Does the child understand that, if A is longer than B and B is longer than C, then A is longer than C? In Piaget's theory, concrete operational thinkers who are capable of transitivity do; preoperational thinkers do not.

concrete operational stage The third Piagetian stage, which lasts from approximately 7 to 11 years of age; children can perform concrete operations, and logical reasoning replaces intuitive reasoning as long as the reasoning can be applied to specific or concrete examples.

seriation The concrete operation that involves ordering stimuli along a quantitative dimension (such as length).

transitivity The ability to logically combine relations to understand certain conclusions. Piaget argued that an understanding of transitivity is characteristic of concrete operational thought.

formal operational stage The fourth and final Piagetian stage, which appears between the ages of 11 and 15; individuals move beyond concrete experiences and think in more abstract and logical ways.

FORMAL OPERATIONAL STAGE

So far we have studied the first three of Piaget's stages of cognitive development: sensorimotor, preoperational, and concrete operational. What are the characteristics of the fourth and final stage?

The **formal operational stage,** which appears between 11 and 15 years of age, is the fourth and final Piagetian stage. In this stage, individuals move beyond concrete experiences and think in abstract and more logical ways. As part of thinking more abstractly, adolescents develop images of ideal circumstances. They might think about what an ideal parent is like and compare their parents to their ideal standards. They begin to entertain possibilities for the future and are fascinated with what they can become. In solving

problems, formal operational thinkers are more systematic and use logical reasoning.

In 2020, across the United States and many countries around the world, the Black Lives Matter protests attracted many adolescents from diverse backgrounds. *Might adolescents' ability to reason hypothetically and to evaluate what is ideal and what is real increase their likelihood of participating in such protests?*
Tom Williams/CQ-Roll Call, Inc/Getty Images

Abstract, Idealistic, and Logical Thinking The abstract quality of the adolescent's thought at the formal operational level is evident in the adolescent's verbal problem-solving ability. Whereas the concrete operational thinker needs to see the concrete elements A, B, and C to be able to make the logical inference that if A = B and B = C, then A = C, the formal operational thinker can solve this problem merely through verbal presentation.

Another indication of the abstract quality of adolescents' thought is their increased tendency to think about thought itself. One adolescent commented, "I began thinking about why I was thinking about what I was. Then I began thinking about why I was thinking about what I was thinking about what I was." If this sounds abstract, it is, and it characterizes the adolescent's enhanced focus on thought and its abstract qualities.

Accompanying the abstract nature of formal operational thought in adolescence is thought full of idealism and possibilities. Although children frequently think in concrete ways, or in terms of what is real and limited, adolescents begin to engage in extended speculation about ideal characteristics—qualities they desire in themselves and in others. Such thoughts often lead adolescents to compare themselves with others in regard to such ideal standards. And the thoughts of adolescents are often fantasy flights into future possibilities. It is not unusual for the adolescent to become impatient with these newfound ideal standards and to become perplexed over which of many ideal standards to adopt.

Many adolescent girls spend long hours in front of the mirror, depleting bottles of hair spray, tubes of lipstick, and jars of cosmetics. *How might this behavior be related to changes in adolescent cognitive and physical development?*
Image Source/Getty Images

As adolescents are learning to think more abstractly and idealistically, they are also learning to think more logically. Children are more likely to solve problems in a trial-and-error fashion. Adolescents begin to think more as a scientist thinks, devising plans to solve problems and systematically testing solutions. They use **hypothetical-deductive reasoning**—that is, they develop hypotheses, or best guesses, and systematically deduce (or conclude) which is the best path to follow in solving the problem.

Assimilation (incorporating new information into existing knowledge) dominates the initial development of formal operational thought, and these thinkers perceive the world subjectively and idealistically. Later in adolescence, as intellectual balance is restored, these individuals accommodate to the cognitive upheaval that has occurred (they adjust to the new information).

Some of Piaget's ideas on formal operational thought are being challenged, however (Reyna & Zayas, 2014). There is much more individual variation in formal operational thought than Piaget envisioned (Kuhn, 2009). Only about one in three young adolescents is a formal operational thinker. Many American adults never become formal operational thinkers, and neither do many adults in other cultures.

Adolescent Egocentrism In addition to thinking more logically, abstractly, and idealistically—characteristics of Piaget's formal operational thought stage—in what other ways do adolescents change cognitively? David Elkind (1978) described how adolescent egocentrism governs the way that adolescents think about social matters. **Adolescent egocentrism** is the heightened self-consciousness of adolescents, which is reflected in their belief that others are as interested in them as they are themselves, and in their sense of personal uniqueness and invincibility. Elkind argued that adolescent egocentrism can be dissected into two types of social thinking—imaginary audience and personal fable.

The **imaginary audience** refers to the aspect of adolescent egocentrism that involves feeling that one is the center of everyone's attention and sensing that one is on stage. An adolescent boy might think that others are as aware as he is of a few hairs that are out of place. An adolescent girl walks into her classroom and thinks that all eyes are riveted on her complexion. Adolescents especially sense that they are "on stage" in early adolescence, believing they are the main actors and all others are the audience. Might the use of social media increase adolescent egocentrism? See *Connecting Development to Life* to explore this topic.

hypothetical-deductive reasoning Piaget's formal operational concept that adolescents have the cognitive ability to develop hypotheses about ways to solve problems and can systematically deduce which is the best path to follow in solving the problem.

adolescent egocentrism The heightened self-consciousness of adolescents, which is reflected in adolescents' beliefs that others are as interested in them as they are themselves, and in adolescents' sense of personal uniqueness and invincibility.

imaginary audience That aspect of adolescent egocentrism that involves feeling that one is the center of attention and sensing that one is on stage.

connecting development to life

Are Social Media an Amplification Tool for Adolescent Egocentrism?

Earlier generations of adolescents did not have social media to connect with large numbers of people; instead, they connected with fewer people, either in person or via telephone. Might today's teens be drawn to social media and its virtually unlimited friend base to express their imaginary audience and sense of uniqueness? A research analysis concluded that amassing a large number of friends (audience) may help to validate adolescents' perception that their life is on stage and everyone is watching them (Psychster Inc, 2010). A look at a teen's home Twitter® comments may suggest to many adults that what teens are reporting is often rather mundane and uninteresting as they update to the world at large what they are doing and having, such as: "Studying heavy. Not happy tonight." or "At Starbucks with Jesse. Lattes are great." Possibly for adolescents, though, such tweets are not trivial but rather an expression of the personal fable's sense of uniqueness (Psychster Inc, 2010).

One study of social networking sites found that the indiscriminate monologue communication from one to many, in which the diverse interests of others are not considered, that often occurs on such sites as Facebook® may produce an egocentric tendency that undermines prosocial behavior (Chiou, Chen, & Liao, 2014). A recent meta-analysis concluded that a greater use of social networking sites was linked to a higher level of narcissism (Gnambs & Appel, 2018).

In what ways might frequent use of social media, such as Facebook®, influence adolescents' cognitive development?
Andrey_Popov/Shutterstock

According to Elkind, the **personal fable** is the part of adolescent egocentrism that involves an adolescent's sense of personal uniqueness and invincibility. Adolescents' sense of personal uniqueness makes them believe that no one can understand how they really feel. For example, an adolescent girl thinks that her mother cannot possibly sense the hurt she feels because her boyfriend has broken up with her. As part of their effort to retain a sense of personal uniqueness, adolescents might craft stories about themselves that are filled with fantasy, immersing themselves in a world that is far removed from reality. Personal fables frequently show up in adolescent diaries.

One study of sixth- through twelfth-graders revealed that a sense of invincibility was linked to risky behaviors such as smoking cigarettes, drinking alcohol, and engaging in juvenile delinquency, whereas a sense of personal uniqueness was related to depression and suicidal thoughts (Aalsma, Lapsley, & Flannery, 2006). Also, in a recent study of teenage motorcycle gangs in Indonesia, their sense of invulnerability was strongly linked to how aggressive they were (Saudi, Hartini, & Bahar, 2018). However, some research studies suggest that, rather than perceiving themselves to be invulnerable, many adolescents view themselves as vulnerable (Reyna & Rivers, 2008). For example, in one study, 12- to 18-year-olds were asked about their chances of dying in the next year and prior to age 20 (Fischhoff & others, 2010). The adolescents greatly overestimated their chances of dying.

Some researchers have questioned the view that invulnerability is a unitary concept and argued rather that it consists of two dimensions (Duggan, Lapsley, & Norman, 2000; Lapsley & Hill, 2010):

- *Danger invulnerability,* which involves adolescents' sense of indestructibility and tendency to take on physical risks (driving recklessly at high speeds, for example)
- *Psychological invulnerability*, which captures an adolescent's felt invulnerability related to personal or psychological distress (getting one's feelings hurt, for example)

personal fable The part of adolescent egocentrism that involves an adolescent's sense of personal uniqueness and invincibility.

One study revealed that adolescents who scored high on a danger invulnerability scale were more likely to engage in juvenile delinquency or substance abuse, or to be depressed

(Lapsley & Hill, 2010). In this study, adolescents who scored high on psychological invulnerability were less likely to be depressed, had higher self-esteem, and maintained better interpersonal relationships. In terms of psychological invulnerability, adolescents often benefit from the normal developmental challenges of exploring identity options, making new friends, asking someone to go out on a date, and learning a new skill. All of these important adolescent tasks involve risk and failure as an option but, if successful, result in enhanced self-image.

Piaget and Education

Evaluating Piaget's Theory

What are some applications of Piaget's theory to education? What are the main contributions and criticisms of Piaget's theory?

PIAGET AND EDUCATION

Piaget was not an educator, but he provided a sound conceptual framework for viewing learning and education. Here are some ideas in Piaget's theory that can be applied to teaching children (Elkind, 1976; Heuwinkel, 1996):

1. *Take a constructivist approach*. Piaget emphasized that children learn best when they are active and seek solutions for themselves. Piaget opposed teaching methods that treat children as passive receptacles for knowledge. The educational implication of Piaget's view is that, in all subjects, students learn best by making discoveries, reflecting on them, and discussing them, rather than by blindly imitating the teacher or doing things by rote.
2. *Facilitate rather than direct learning*. Effective teachers design situations that allow students to learn by doing. These situations promote students' thinking and discovery. Teachers listen, watch, and question students, to help them gain better understanding.
3. *Consider the child's knowledge and level of thinking*. Students do not come to class with empty minds. They have concepts of space, time, quantity, and causality. These ideas

What are some educational strategies that can be derived from Piaget's theory?
Fuse/Corbis/Getty Images

differ from the ideas of adults. Teachers need to interpret what a student is saying and respond in a way that is not too far from the student's level. Also, Piaget suggested that it is important to examine children's mistakes in thinking, not just what they get correct, to help guide them to a higher level of understanding.

4. *Promote the student's intellectual health*. When Piaget came to lecture in the United States, he was asked, "What can I do to get my child to a higher cognitive stage sooner?" He was asked this question so often here compared with other countries that he called it the American question. Piaget emphasized that children's learning should occur naturally. Children should not be pushed and pressured into achieving too much too early in their development, before they are maturationally ready. Some parents spend long hours every day holding up large flash cards with words on them to improve their baby's vocabulary. In the Piagetian view, this is not an effective way for infants to learn. It places too much emphasis on speeding up intellectual development, involves passive learning, and will not lead to positive outcomes.
5. *Turn the classroom into a setting of exploration and discovery*. What do actual classrooms look like when the teachers adopt Piaget's views? Several first- and second-grade math classrooms provide some good examples (Kamii, 1985, 1989). The teachers emphasize students' own exploration and discovery. The classrooms are less structured than we would expect in a typical classroom. Workbooks and predetermined assignments are not used. Rather, the teachers observe the students' interests and natural participation in activities to determine what the course of learning will be. For example, a math lesson might be constructed around counting the day's lunch money or dividing supplies among students. Often, games are prominently used in the classroom to stimulate mathematical thinking. For example, a version of dominoes teaches children about even-numbered combinations. A variation on tic-tac-toe involves replacing Xs and Os with numbers. Teachers encourage peer interaction during the lessons and games because students' different viewpoints can contribute to advances in thinking.

EVALUATING PIAGET'S THEORY

What were Piaget's main contributions? Has his theory withstood the test of time?

Piaget's Contributions Piaget, the founder of the study of children's cognitive development, was a giant in the field of developmental psychology (Miller, 2015). Psychologists are indebted to him for devising a long list of masterful concepts of enduring power and fascination: assimilation, accommodation, object permanence, egocentrism, conservation, and others. Psychologists also owe him for instilling the current vision of children as active, constructive thinkers. And they have a debt to him for creating a theory that has generated a huge volume of research on children's cognitive development.

Piaget also was a genius when it came to observing children. His careful observations showed us inventive ways to discover how children act on and adapt to their world. Piaget pointed out some important things to look for in cognitive development, such as the shift from preoperational to concrete operational thinking. He also showed us how children need to make their experiences fit their schemes (cognitive frameworks) yet simultaneously adapt their schemes to fit their experiences. Piaget revealed that cognitive change is more likely to occur if the context is structured to allow gradual movement to the next higher level. Concepts do not emerge suddenly, full-blown, but instead develop through a series of partial accomplishments that lead to increasingly comprehensive understanding.

Criticisms of Piaget's Theory Piaget's theory has not gone unchallenged (Miller, 2015). Questions are raised about estimates of children's competence at different developmental levels, stages, the training of children to reason at higher levels, and culture and education.

Estimates of Children's Competence Researchers have found that some cognitive abilities emerge earlier than Piaget thought (Bell & Broomell, 2021; Oakes, 2021). For example, as previously noted, some aspects of object permanence emerge earlier than he believed (Baillargeon, 2016). Even 2-year-olds are nonegocentric in some contexts. When they realize that another person does not see an object, they investigate whether the person is blindfolded or looking in a different direction. Some understanding of the conservation of number has been demonstrated as early as age 3, although Piaget did not think it emerged until age 7. Young children are not as uniformly "pre" this and "pre" that (preoperational, for example) as Piaget thought.

Other cognitive abilities also can emerge later than Piaget thought (Kuhn, 2011). Many adolescents still think in concrete operational ways or are just beginning to master formal operations. Even many adults are not formal operational thinkers. In sum, recent theoretical revisions highlight more cognitive competencies of infants and young children (Newcombe, 2021) and more cognitive shortcomings of adolescents and adults (Mercurio & others, 2020).

Stages Children's cognitive development is not as stage-like as Piaget envisioned (Hayne & Herbert, 2021). Because some cognitive abilities have been found to emerge earlier than Piaget thought, and others later, children do not appear to move cleanly from one stage to another. Other evidence casting doubt on the stage notion is that children often show more understanding on one task than on another similar task.

Effects of Training Some children who are at one cognitive stage (such as preoperational) can be trained to reason at a higher cognitive stage (such as concrete operational). This discovery poses a problem for Piaget's theory. He argued that such training is only superficial and ineffective unless the child is at a maturational transition point between the stages (Gelman & Williams, 1998).

Culture and Education Culture and education exert stronger influences on children's development than Piaget maintained (Kirmeyer & others, 2021; Riccio & Castro, 2021). For example, the age at which children acquire conservation skills is related to how much practice their culture provides in these skills. An outstanding teacher who provides instruction in the logic of math and science can promote concrete and formal operational thought.

An Alternative View **Neo-Piagetians** argue that Piaget got some things right but that his theory needs considerable revision. They give more emphasis to how children use attention, memory, and strategies to process information (Case, 1987, 1999). They especially stress that a more accurate portrayal of children's thinking requires attention to children's strategies and other cognitive skills, such as inhibition; the speed at which children process information; the specific task involved; and the division of problems into smaller, more precise steps (Chevalier, Dauvier, & Blaye, 2018). In the chapter on "Information Processing," we further discuss these aspects of children's thought.

An outstanding teacher and education in the logic of science and mathematics are important cultural experiences that promote the development of operational thought. *Might Piaget have underestimated the roles of culture and schooling in children's cognitive development?*

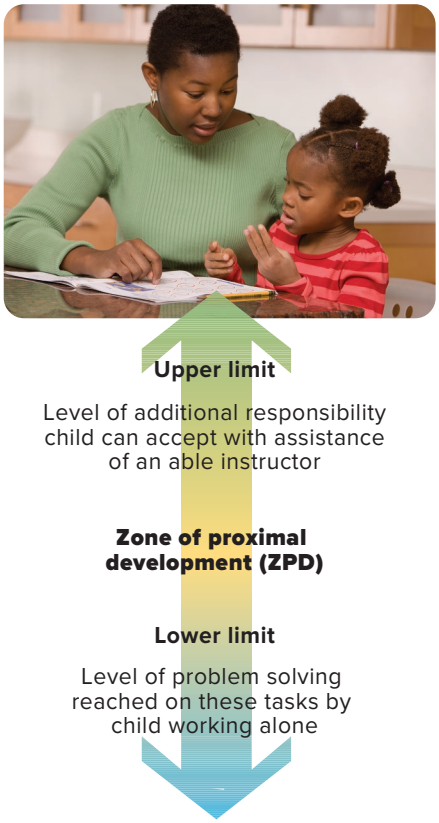
3 Vygotsky's Theory of Cognitive Development

LG3 Identify the main concepts in Vygotsky's theory, and compare it with Piaget's theory.

The Zone of Proximal Development | Scaffolding | Language and Thought | Teaching Strategies | Evaluating Vygotsky's Theory

zone of proximal development (ZPD) Vygotsky's term for tasks that are too difficult for children to master alone but can be mastered with guidance and assistance from adults or more-skilled children.

scaffolding In cognitive development, a term Vygotsky used to describe the changing level of support over the course of a teaching session, with the more-skilled person adjusting guidance to fit the child's current performance level.



Upper limit
Level of additional responsibility child can accept with assistance of an able instructor
Zone of proximal development (ZPD)
Lower limit
Level of problem solving reached on these tasks by child working alone

FIGURE 9

VYGOTSKY'S ZONE OF PROXIMAL DEVELOPMENT. Vygotsky's zone of proximal development has a lower limit and an upper limit. Tasks in the ZPD are too difficult for the child to perform alone. They require assistance from an adult or a more-skilled child. As children experience the verbal instruction or demonstration, they organize the information in their existing mental structures so they can eventually perform the skill or task alone.

Ariel Skelley/Blend Images LLC

Piaget's theory is a major developmental theory. Another developmental theory that focuses on children's cognition is Vygotsky's theory. Like Piaget, Lev Vygotsky emphasized that children actively construct their knowledge and understanding (Esteban-Guitart, 2018). In Piaget's theory, children develop ways of thinking and understanding by their actions and interactions with the physical world. In Vygtosky's theory, children are more often described as social creatures than in Piaget's theory (Yu & Hu, 2017). They develop their ways of thinking and understanding primarily through social interaction (Clara, 2017). Their cognitive development depends on the tools provided by society, and their minds are shaped by the cultural context in which they live (Baggs & Chemero, 2020).

We briefly described Vygotsky's theory in the chapter titled "Introduction." Here we take a closer look at his ideas about how children learn and his view of the role of language in cognitive development.

THE ZONE OF PROXIMAL DEVELOPMENT

Vygotsky's belief in the importance of social influences, especially instruction, to children's cognitive development is reflected in his concept of the zone of proximal development (Kantar, Ezzeddine, & Rizk, 2020). **Zone of proximal development (ZPD)** is Vygotsky's term for the range of tasks that are too difficult for the child to master alone but that can be learned with guidance and assistance from adults or more-skilled children. Thus, the lower limit of the ZPD is the level of skill reached by the child working independently. The upper limit is the level of additional responsibility the child can accept with the assistance of an able instructor (see Figure 9). The ZPD captures the child's cognitive skills that are in the process of maturing and can be accomplished only with the assistance of a more-skilled person (Groot & others, 2020). Vygotsky (1962) called these the "buds" or "flowers" of development, to distinguish them from the "fruits" of development, which the child already can accomplish independently.

What are some factors that can influence the effectiveness of the ZPD in children's learning and development? Researchers have found that the ZPD's effectiveness is enhanced by factors such as better emotion regulation, secure attachment, absence of maternal depression, and child compliance (Gauvain, 2013).

SCAFFOLDING

Closely linked to the idea of the ZPD is the concept of scaffolding. **Scaffolding** means changing the level of support. Over the course of a teaching session, a more-skilled person (a teacher or advanced peer) adjusts the amount of guidance to fit the child's current performance (Daniels, 2017). When the student is learning a new task, the skilled person may use direct instruction. As the student's competence increases, the person gives less guidance. One study found that scaffolding techniques that heightened engagement, encouraged direct exploration, and facilitated "sense-making," such as guided play, improved 4- to 5-year-old children's acquisition of geometric knowledge (Fisher & others, 2013).

Dialogue is an important tool of scaffolding in the zone of proximal development. Vygotsky viewed children as having rich but unsystematic, disorganized, and spontaneous concepts. In a dialogue, these concepts meet with the skilled helper's more systematic, logical, and rational concepts. As a result, the child's concepts become more systematic, logical, and rational. For example, a dialogue might take place between a teacher and a child when the teacher uses scaffolding to help a child understand a concept like "transportation."

LANGUAGE AND THOUGHT

The use of dialogue as a tool for scaffolding is only one example of the important role of language in a child's development. According to Vygotsky, children use speech not only for social communication but also to help them solve tasks (Vasileva & Balyasnikova, 2019). Vygotsky (1962) further believed that young children use language to plan, guide, and monitor their behavior. This use of language for self-regulation is called private speech (van der Veer & Zavershneva, 2018). For Piaget, private speech is egocentric and immature—but for Vygotsky, it is an important tool of thought during early childhood (Lantolf, 2017).

Vygotsky said that language and thought initially develop independently of each other and then merge. He emphasized that all mental functions have external, or social, origins (Erbil, 2020). Children must use language to communicate with others before they can focus inward on their own thoughts. Children also must communicate externally and use language for a long period of time before they can make the transition from external to internal speech. This transition period occurs between 3 and 7 years of age and involves talking to oneself. After a while, the self-talk becomes second nature to children, and they can act without verbalizing; at this point, children have internalized their egocentric speech in the form of *inner speech*, which becomes their thoughts (Mercer, 2008).

Vygotsky held that children who use a lot of private speech are more socially competent than those who don't (van der Veer & Zavershneva, 2018). He argued that private speech represents an early transition in becoming more socially communicative. For Vygotsky, when young children talk to themselves, they are using language to govern their behavior and guide themselves (Vissers, Tomas, & Law, 2020). For example, a child working on a puzzle might say to herself, "Which pieces should I put together first? I'll try those green ones first. Now I need some blue ones. No, that blue one doesn't fit there. I'll try it over here."

Piaget maintained that self-talk is egocentric and reflects immaturity. However, researchers have found support for Vygotsky's view that private speech plays a positive role in children's development (Vissers, Tomas, & Law, 2020). Researchers have found that children use private speech more often when tasks are difficult, when they have made errors, and when they are not sure how to proceed (Berk, 1994). They also have discovered that children who use private speech are more attentive and improve their performance more than children who do not use private speech (Berk & Spuhl, 1995). Also, in one study, children's private speech was linked to an increase in emotion regulation (Day & Smith, 2013). And a recent study indicated that mothers who engage in sensitive parenting have children who use more private speech (Day & Smith, 2019).

Lev Vygotsky (1896–1934), shown here with his daughter, reasoned that children's cognitive development is advanced through social interaction with more-skilled individuals embedded in a sociocultural backdrop. *How is Vygotsky's theory different from Piaget's?*

TEACHING STRATEGIES

Vygotsky's theory has been embraced by many teachers and has been successfully applied to education (Daniels, 2017; Holzman, 2017). Here are some ways Vygotsky's theory can be incorporated in classrooms:

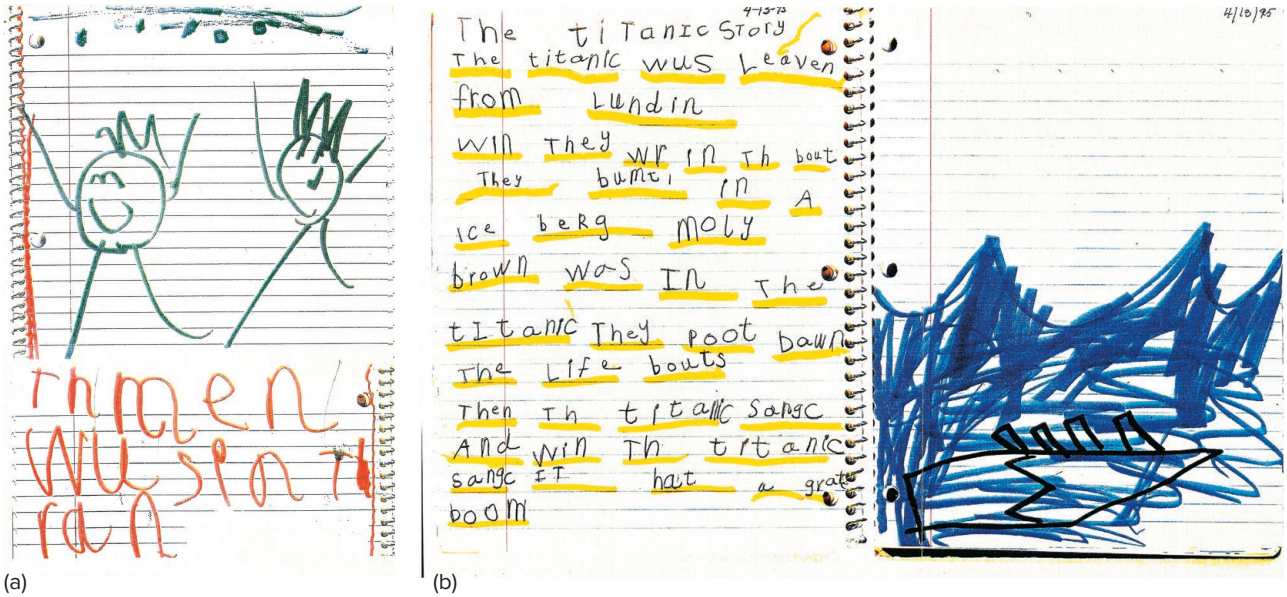
1. *Use the child's ZPD in teaching*. Teaching should begin near the zone's upper limit, so that the child can reach the goal with help and move to a higher level of skill and knowledge. Offer just enough assistance. You might ask, "What can I do to help you?" or simply observe the child's intentions and attempts and provide support when needed. When the child hesitates, offer encouragement. And encourage the child to practice the skill. You may watch and appreciate the child's practice or offer support when the child forgets what to do.
2. *Use more-skilled peers as teachers*. Remember that it is not just adults who are important in helping children learn. Children also benefit from the support and guidance of more-skilled children.
3. *Monitor and encourage children's use of private speech*. Be aware of the developmental change from externally talking to oneself when solving a problem during the preschool years, to privately talking to oneself in the early elementary school years (Mercer, 2008). In the elementary school years, encourage children to internalize and self-regulate their talk to themselves.
4. *Place instruction in a meaningful context*. Educators today are moving away from abstract presentations of material, instead providing students with opportunities to experience learning in real-world settings. For example, instead of just memorizing math formulas, students work on math problems with real-world implications.

How can Vygotsky's ideas be applied to educating children?
IT Stock Free/Alamy Stock Photo

5. *Transform the classroom with Vygotskian ideas.* Tools of the Mind is an early childhood education curriculum that emphasizes children's development of self-regulation and the cognitive foundations of literacy (Shaheen, 2014). The curriculum was created by Elena Bodrova and Deborah Leong (2007, 2015a, b) and has been implemented in more than 200 classrooms. Most of the children in the Tools of the Mind programs are at risk because of their living circumstances, which in many instances involve poverty and other difficult conditions such as being homeless and having parents with drug problems.

Tools of the Mind is grounded in Vygotsky's (1962) theory, with special attention given to cultural tools and developing self-regulation, the zone of proximal development, scaffolding, private speech, shared activity, and play as important activity. In a Tools of the Mind classroom, dramatic play has a central role. Teachers guide children in creating themes that are based on the children's interests, such as treasure hunt, store, hospital, and restaurant. Teachers also incorporate field trips, visitor presentations, videos, and books in the development of children's play. In addition, they help children develop a play plan, which increases the maturity of their play. Play plans describe what the children expect to do in the play period, including the imaginary context, roles, and props to be used. The play plans increase the quality of children's play and self-regulation.

Scaffolding writing is another important theme in the Tools of the Mind classroom. Teachers guide children in planning their own message by drawing a line to stand for each word the child says. Children then repeat the message, pointing to each line as they say the word. Then, a child writes on the lines, trying to represent each word with some letters or symbols. Figure 10 shows how the scaffolding writing process improved a 5-year-old child's writing over the course of two months. Research assessments of children's writing in Tools of the Mind classrooms revealed that children in the program have more advanced writing skills than children in other early childhood programs (Bodrova & Leong, 2007, 2015a, b) (see Figure 10). For example, they write more complex messages, use more words, spell more accurately, show better letter recognition, and have a better understanding of the concept of a sentence. The effectiveness of the Tools of the Mind approach also was examined in another study of 29 schools,



(a) (b)

FIGURE 10

WRITING PROGRESS OF A 5-YEAR-OLD BOY OVER TWO MONTHS USING THE SCAFFOLDING WRITING PROCESS IN TOOLS OF THE MIND. (*a*) Five-year-old Aaron's independent journal writing prior to using the scaffolded writing technique. (*b*) Aaron's journal after two months of using the scaffolded writing technique.
Bodrova, Elena and Leong, Deborah J. "Tools of the Mind: A Case Study of Implementing the Vygotskian Approach in American Early Childhood and Primary Classrooms," Geneva, Switzerland: International Bureau of Education, 2001, 36–38.

79 classrooms, and 759 students (Blair & Raver, 2014). Positive effects of the Tools of the Mind program were found for the cognitive processes of executive function (improved self-regulation, for example) and attention control. Further, the Tools of the Mind program improved children's reading, vocabulary, and mathematics at the end of kindergarten and into the first grade. The most significant improvements occurred in high-poverty schools.

EVALUATING VYGOTSKY'S THEORY

Even though their theories were proposed at about the same time, most of the world learned about Vygotsky's theory later than they learned about Piaget's theory, so Vygotsky's theory has not yet been evaluated as thoroughly. Vygotsky's view of the importance of sociocultural influences on children's development fits with the current belief that it is important to evaluate the contextual factors in learning (Baggs & Chemero, 2020).

We already have considered several contrasts between Vygotsky's and Piaget's theories, such as Vygotsky's emphasis on the importance of private speech in development and Piaget's view that such speech is immature. Although both theories are constructivist, Vygotsky's is a **social constructivist approach,** which emphasizes the social contexts of learning and the construction of knowledge through social interaction (Yu & Hu, 2017).

In moving from Piaget to Vygotsky, the conceptual shift is from the individual to collaboration, social interaction, and sociocultural activity (Erbil, 2020). The endpoint of cognitive development for Piaget is formal operational thought. For Vygotsky, the endpoint can differ, depending on which skills are considered to be the most important in a particular culture. For Piaget, children construct knowledge by transforming, organizing, and reorganizing previous knowledge. For Vygotsky, children construct knowledge through social interaction (Daniels, 2017). The implication of Piaget's theory for teaching is that children need support to explore their world and discover knowledge. The main implication of Vygotsky's theory for teaching is that students need many opportunities to learn with the teacher and more-skilled peers. In both Piaget's and Vygotsky's theories, teachers serve as facilitators and guides, rather than as directors and molders of learning. Figure 11 compares Vygotsky's and Piaget's theories.

Criticisms of Vygotsky's theory also have surfaced. Some critics point out that Vygotsky was not specific enough about age-related changes. Another criticism focuses on Vygotsky not adequately describing how changes in socioemotional capabilities contribute to cognitive

developmental **connection**
Education
Whether to follow a constructivist or direct instruction approach is a major educational issue. Connect to "Schools, Achievement, and Work."

social constructivist approach An emphasis on the social contexts of learning and construction of knowledge through social interaction. Vygotsky's theory reflects this approach.

	Vygotsky	Piaget
Sociocultural Context	Strong emphasis	Little emphasis
Constructivism	Social constructivist	Cognitive constructivist
Stages	No general stages of development proposed	Strong emphasis on stages (sensorimotor, preoperational, concrete operational, and formal operational)
Key Processes	Zone of proximal development, language, dialogue, tools of the culture	Schema, assimilation, accommodation, operations, conservation, classification
Role of Language	A major role; language plays a powerful role in shaping thought	Language has a minimal role; cognition primarily directs language
View on Education	Education plays a central role, helping children learn the tools of the culture	Education merely refines the child's cognitive skills that have already emerged
Teaching Implications	Teacher is a facilitator and guide, not a director; establish many opportunities for children to learn with the teacher and more-skilled peers	Also views teacher as a facilitator and guide, not a director; provide support for children to explore their world and discover knowledge

FIGURE **11**

COMPARISON OF VYGOTSKY'S AND PIAGET'S THEORIES.

development (Gauvain & Perez, 2015). Yet another criticism is that he overemphasized the role of language in thinking. Also, his emphasis on collaboration and guidance has potential pitfalls. Might facilitators be too helpful in some cases, as when a parent becomes overbearing and controlling? Further, some children might become lazy and expect help when they could have done something on their own.

4 Cognitive Changes in Adulthood

LG4 Describe cognitive changes in adulthood.

Piaget's View | Realistic and Pragmatic Thinking | Reflective and Relativistic Thinking | Cognition and Emotion | Is There a Fifth, Postformal Stage? | Are There Cognitive Stages in Middle and Late Adulthood?

We have discussed the theories that Piaget and Vygotsky proposed to account for how the cognitive development of children proceeds. Neither, however, had much to say about cognitive development in adulthood. What do developmentalists know about changes in the way that adults think?

PIAGET'S VIEW

Recall that, according to Piaget, the formal operational stage of thought begins at 11 to 15 years of age. During this stage, the final one in Piaget's theory, thinking becomes more abstract, idealistic, and logical than the concrete operational thinking of 7- to 11-year-olds. Of course, young adults have more knowledge than adolescents. But, according to Piaget, adults and adolescents use the same type of reasoning. Adolescents and adults think in qualitatively the same way.

Many individuals don't reach the highest level of their formal operational thinking until adulthood. That is, though many individuals begin to plan and hypothesize about intellectual problems as adolescents, they become more systematic and sophisticated in applying these skills as young adults. Also, many adults do not think in formal operational ways (Keating, 2004).

REALISTIC AND PRAGMATIC THINKING

Some developmentalists propose that as young adults move into the world of work, their way of thinking does change. One idea is that as they face the constraints of reality that work promotes, their idealism decreases (Labouvie-Vief, 1986).

A related change in thinking was proposed by K. Warner Schaie (1977, 2016). He concluded that it is unlikely that adults go beyond the powerful methods of scientific thinking characteristic of the formal operational stage. However, Schaie argued that adults do progress beyond adolescents in their use of intellect. For example, in early adulthood individuals often switch from acquiring knowledge to applying knowledge as they pursue success in their work.

How might emerging and young adults think differently from adolescents?
Paul Bradbury/Caiaimage/Glow Images

REFLECTIVE AND RELATIVISTIC THINKING

William Perry (1970) also described changes in cognition that take place in early adulthood. He said that adolescents often view the world in terms of polarities—right/wrong, we/they, or good/bad. As youth age into adulthood, they gradually move away from this type of absolutist thinking as they become aware of the diverse opinions and multiple perspectives of others. Thus, in Perry's view, the absolutist, dualistic thinking of adolescence gives way to the reflective, relativistic thinking of adulthood. Other developmentalists also argue that reflective thinking is an important indicator of cognitive change in young adults (Mascalo & Fischer, 2010).

developmental **connection**
Cognitive Theory
Links between cognition and emotion are increasingly being studied. Connect to "Introduction" and "Emotional Development and Attachment."

COGNITION AND EMOTION

Gisela Labouvie-Vief and her colleagues (Labouvie-Vief, 2009; Labouvie-Vief, Gruhn, & Studer, 2010) also argue that to understand cognitive changes in adulthood it is necessary to consider how emotional maturity might affect cognitive development. They conclude that although emerging and young adults become more aware that emotions influence their thinking, at this point thinking is often swayed too strongly by negative emotions that can produce distorted and self-serving conclusions. In their research, a subset of emerging adults who are high in empathy, flexibility, and autonomy are more likely to engage in complex, integrated cognitive-emotional thinking. Labouvie-Vief and her colleagues have found that the ability to think in this cognitively and emotionally balanced, advanced manner increases during middle adulthood. Further, they emphasize that in middle age, individuals become more inwardly reflective and less context-dependent in their thinking than they were as young adults. In the work of Labouvie-Vief and her colleagues, we see the effort to discover connections between cognitive and socioemotional development that is an increasing trend in the field of life-span development.

postformal thought Thinking that is reflective, relativistic, and contextual; provisional; realistic; and influenced by emotions.

IS THERE A FIFTH, POSTFORMAL STAGE?

Some theorists have pieced together these descriptions of adult thinking and have proposed that young adults move into a new qualitative stage of cognitive development—postformal thought (Sinnott, 2003). **Postformal thought** is described as follows:

- *Reflective, relativistic, and contextual.* As young adults engage in solving problems, they might think deeply about many aspects of work, politics, relationships, and other areas of life (Labouvie-Vief, 1986). They find that what might be the best solution to a problem at work (with a boss or co-worker) might not be the best solution at home (with a romantic partner). Thus, postformal thought holds that the correct answer to a problem requires reflective thinking and may vary from one situation to another. Some psychologists argue that reflective thinking continues to increase and becomes more internal and

What characterizes a possible fifth stage of cognitive development called postformal thought?
Yuri Arcurs/Alamy Stock Photo

less contextual in middle age (Labouvie-Vief, Gruhn, & Studer, 2010; Mascalo & Fischer, 2010).

- *Provisional*. Many young adults also become more skeptical about what is presented as absolute truth and seem unwilling to accept an answer as final. Thus, they come to see the search for truth as an ongoing and perhaps never-ending process.
- *Realistic*. Young adults understand that thinking can't always be abstract. In many instances, it must be realistic and pragmatic.
- *Recognized as being influenced by emotion.* Emerging and young adults are more likely than adolescents to understand that their thinking is influenced by emotions. However, too often negative emotions produce thinking that is distorted and self-serving at this point in development.

How strong is the evidence for a fifth, postformal stage of cognitive development? Researchers have found that young adults are more likely to engage in postformal thinking than adolescents are (Commons & Richards, 2003; Commons & others, 1989). But critics argue that research has yet to document that postformal thought is a qualitatively more advanced stage than formal operational thought.

developmental **connection**

Life-Span Perspective

How might wisdom change as individuals go through the adult years? Connect to "Intelligence."

ARE THERE COGNITIVE STAGES IN MIDDLE AND LATE ADULTHOOD?

Adult cognitive stages per se have not been proposed beyond the postformal fifth stage we just discussed. And for the middle and late adulthood periods of development there has been little discussion of what the contents of those stages might be like (Schaie, 2016).

What are some changes in cognitive development that would provide some of the content of a stage-like description of what takes place during middle and late adulthood? Rather than qualitative stage descriptions of cognitive changes in middle and late adulthood, some gradual, quantitative cognitive changes have been proposed and studied. These include fluid and crystallized intelligence, and cognitive mechanics and cognitive pragmatics (Shin & others, 2020).

developmental **connection**

Memory

How does memory change in middle and late adulthood? Connect to "Information Processing."

- *Fluid and Crystallized Intelligence. Fluid intelligence,* the person's ability to reason abstractly, has been theorized to decrease in middle and late adulthood (Horn & Donaldson, 1980). *Crystallized intelligence,* the individual's accumulated information and verbal skills, has been proposed to increase during middle and late adulthood.
- *Cognitive Mechanics and Cognitive Pragmatics. Cognitive mechanics,* linked to biological foundations and brain development, have been hypothesized to decline in middle and late adulthood. Cognitive processes that are components of cognitive mechanics include processing speed, attention, and some aspects of memory. *Cognitive pragmatics,* which are associated with experience and culture, have been proposed to increase during middle and late adulthood. Components of cognitive pragmatics include reading and writing skills, language comprehension, professional skills, and wisdom.

Might there be a cognitive stage that describes middle-aged and/or older adults' cognitive development?
SpeedKingz/Shutterstock

The overlap between fluid intelligence and cognitive mechanics, and the similarities between crystallized intelligence and cognitive pragmatics, have been recognized with the creation of the labels *fluid mechanics* and *crystallized pragmatics* (Lovden & Lindenberger, 2007).

The combination of multiple cognitive processes and abilities in an age-related manner takes on the characteristics of a stage-like description. However, as indicated earlier, at this point a stage of fluid mechanics and crystallized intelligence has not been proposed. Further discussion of these aspects of cognitive development is highlighted in the chapter on "Intelligence."

Current theory and research on changes in adult cognitive development mainly focuses on specific aspects of information processing, such as attention, memory, and thinking, but not on stages of development (Thomas & Gutchess, 2020). In the chapter on "Information Processing" you will read about these specific cognitive processes and how they change during various stages of development. One candidate for possible cognitive improvement in older adults is wisdom.

Cognitive Developmental Approaches

1 Piaget's Theory of Cognitive Development

LG1 Discuss the key processes and four stages in Piaget's theory.

Processes of Development

- In Piaget's theory, children construct their own cognitive worlds, building mental structures to adapt to their world.
- Schemes are actions or mental representations that organize knowledge. Behavioral schemes (physical activities) characterize infancy, whereas mental schemes (cognitive activities) develop in childhood.
- Adaptation involves assimilation and accommodation. Assimilation occurs when children use existing schemes to deal with new information. Accommodation happens when children adjust their schemes to account for new information and experiences. Through organization, children group isolated behaviors into a higher-order, more smoothly functioning cognitive system.
- Equilibration is a mechanism Piaget proposed to explain how children shift from one cognitive stage to the next. As children experience cognitive conflict in trying to understand the world, they seek equilibrium. The result is equilibration, which brings the child to a new stage of thought.
- According to Piaget, there are four qualitatively different stages of thought: sensorimotor, preoperational, concrete operational, and formal operational.

Sensorimotor Stage

- In sensorimotor thought, the first of Piaget's four stages, the infant organizes and coordinates sensations with physical movements. The stage lasts from birth to about 2 years of age.
- Sensorimotor thought has six substages: simple reflexes; primary circular reactions; secondary circular reactions; coordination of secondary circular reactions; tertiary circular reactions, novelty, and curiosity; and internalization of schemes.

- One key aspect of this stage is object permanence, the ability of infants to understand that objects continue to exist even though they are no longer observing them. Another aspect involves infants' understanding of cause and effect.
- In the past several decades, revisions of Piaget's view have been proposed based on research. For example, researchers have found that a stable and differentiated perceptual world is established earlier than Piaget envisioned.

Preoperational Stage

- Preoperational thought is the beginning of the ability to reconstruct at the level of thought what has been established in behavior. It involves a transition from a primitive to a more sophisticated use of symbols. In preoperational thought, the child does not yet think in an operational way.
- The symbolic function substage occurs roughly from 2 to 4 years of age and is characterized by symbolic thought, egocentrism, and animism. The intuitive thought substage stretches from about 4 to 7 years of age. It is called intuitive because children seem sure about their knowledge yet are unaware of how they know what they know.
- The preoperational child lacks conservation and asks a barrage of questions.

Concrete Operational Stage

- Concrete operational thought occurs roughly from 7 to 11 years of age. During this stage, children can perform concrete operations, think logically about concrete objects, classify things, and reason about relationships among classes of things. Concrete thought is not as abstract as formal operational thought.

Formal Operational Stage

- Formal operational thought appears between 11 and 15 years of age. Formal operational thought is more abstract, idealistic, and logical than concrete operational thought.
- Piaget argues that adolescents become capable of engaging in hypothetical-deductive reasoning. But Piaget did not give adequate attention to individual variations in adolescent thinking. Many young adolescents do not think in hypothetical-deductive ways but rather are consolidating their concrete operational thinking. In addition, adolescents develop a special kind of egocentrism that involves an imaginary audience and a personal fable about being unique and invulnerable.

2 Applying and Evaluating Piaget's Theory

LG2 Apply Piaget's theory to education, and evaluate Piaget's theory.

Piaget and Education

- Piaget was not an educator, but his constructivist views have been applied to teaching. These applications include an emphasis on facilitating rather than directing learning, considering the child's level of knowledge, using ongoing assessment, promoting the student's intellectual health, and turning the classroom into a setting for exploration and discovery.

Evaluating Piaget's Theory

- We are indebted to Piaget for establishing the field of cognitive development. He was a genius at observing children, and he gave us a number of masterful concepts. Critics, however, question his estimates of competence at different developmental levels, his stage concept, and other ideas. Neo-Piagetians emphasize the importance of information processing.

3 Vygotsky's Theory of Cognitive Development

LG3 Identify the main concepts in Vygotsky's theory, and compare it with Piaget's theory.

The Zone of Proximal Development

- Zone of proximal development (ZPD) is Vygotsky's term for the range of tasks that are too difficult for children to master alone but that can be learned with the guidance and assistance of more-skilled adults and peers.

Scaffolding

- Scaffolding is a teaching technique in which a more-skilled person adjusts the level of guidance to fit the child's current performance level. Dialogue is an important aspect of scaffolding.

Language and Thought

- Vygotsky argued that language plays a key role in cognition. Language and thought initially develop independently, but then children internalize their egocentric speech in the form of inner speech, which becomes their thoughts. This transition to inner speech occurs between 3 and 7 years of age. Vygotsky's view contrasts with Piaget's view that young children's self-talk is immature and egocentric.

Teaching Strategies

- Applications of Vygotsky's ideas to education include using the child's zone of proximal development and scaffolding, using more-skilled peers as teachers, monitoring and encouraging children's use of private speech, and accurately assessing the zone of proximal development.
- The Tools of the Mind curriculum reflects the Vygotskian approach. These practices can transform the classroom and establish a meaningful context for instruction.

Evaluating Vygotsky's Theory

- Like Piaget, Vygotsky emphasized that children actively construct their understanding of the world. Unlike Piaget, he did not propose stages of cognitive development, and he emphasized that children construct knowledge through social interaction. In Vygotsky's theory, children depend on tools provided by the culture, which determines which skills they will develop. Some critics say that Vygotsky overemphasized the role of language in thinking.

4 Cognitive Changes in Adulthood LG4 Describe cognitive changes in adulthood.

Piaget's View

- Piaget said that formal operational thought, entered at 11 to 15 years of age, is the final cognitive stage, although adults are more knowledgeable than adolescents.

Realistic and Pragmatic Thinking

- Some experts argue that the idealism of Piaget's formal operational stage declines in young adults, being replaced by more realistic, pragmatic thinking.

Reflective and Relativistic Thinking

- Perry said that adolescents often engage in dualistic, absolutist thinking, whereas young adults are more likely to think reflectively and relativistically.

Cognition and Emotion

- Emerging and young adults become more aware that emotions influence their thinking. However, at this point in development, negative emotions often produce distorted and self-serving thinking that interferes with achieving an integrated, complex understanding of the link between cognition and emotion. Nonetheless, a subset of emotionally mature emerging and young adults achieve this understanding.

Is There a Fifth, Postformal Stage?

- A fifth, postformal stage that has been proposed is postformal thought, which is reflective, relativistic, and contextual; provisional; realistic; and influenced by emotions.

Are There Cognitive Stages in Middle and Late Adulthood?

- No cognitive stages per se have been proposed for middle and late adulthood, although the concepts of fluid mechanics and crystallized pragmatics take on stage-like characteristics. Theory and research today in adult cognitive development focuses mainly on specific aspects of information processing rather than on cognitive stages.

preview

What do people notice in their environment? What do they remember? And how do they think about it? Questions like these characterize the information-processing approach to cognitive development. Researchers who take this approach usually do not describe individuals as being in one stage of cognitive development or another. Instead, they describe and analyze how the speed of processing information, attention, memory, thinking, and metacognition change over time.

1 The Information-Processing Approach

LG1 Explain the information-processing approach and its application to development.

The Information-Processing Approach and Its Application to Development

Speed of Processing Information

What are some of the basic ideas of the information-processing approach? How does information processing change as individuals develop? How important is speed of processing at various points in development?

THE INFORMATION-PROCESSING APPROACH AND ITS APPLICATION TO DEVELOPMENT

The *information-processing approach* analyzes how individuals encode information, manipulate it, monitor it, and create strategies for handling it (Siegler & Alabali, 2020). This approach shares some characteristics with the theories of cognitive development discussed in the chapter on "Cognitive Developmental Approaches." Those theories and the information-processing approach rejected Skinner's behavioral approach, which dominated psychology during the first half of the twentieth century. The behaviorists argued that to explain behavior it is important to examine associations between stimuli and behavior. In contrast, the information-processing approach—like the theories of Piaget and Vygotsky—focuses on how people think (Dotan, Eliahou, & Cohen, 2021).

Cognitive psychologists often use the computer as an analogy to help explain the connection between cognition and the brain (Goldstein, 2019). They describe the physical brain as the computer's hardware and cognition as its software. In this analogy, the sensory and perceptual systems provide an "input channel" similar to the way data are entered into the computer (see Figure 1). As input (information) comes into the mind, mental processes, or operations, act on it, just as the computer's software acts on the data. The transformed input generates information that remains in memory much in the way a computer stores what it has worked on. Finally, the information is retrieved from memory and "printed out" or "displayed" (so to speak) as an observable response.

Computers provide a logical and concrete, but oversimplified, model of the mind's processing of

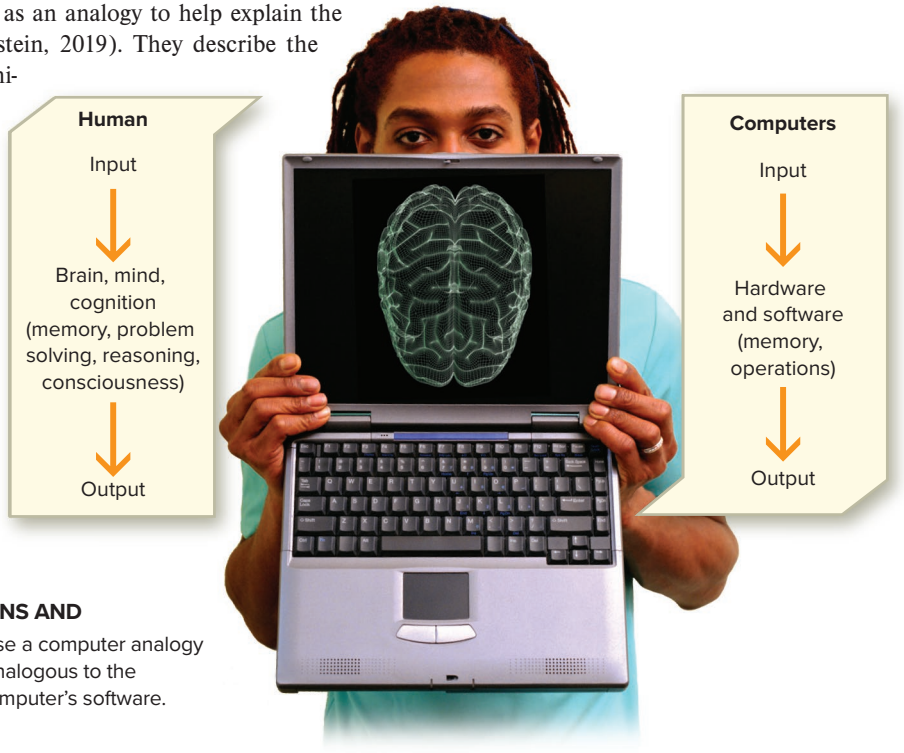

FIGURE 1

information. Inanimate computers and human brains function quite differently in some respects. For example, most computers receive information from a human who has already coded the information and removed much of its ambiguity. In contrast, each brain cell, or neuron, can respond to ambiguous information transmitted through sensory receptors such as the eyes and ears.

Computers can do some things better than humans. For instance, computers can perform complex numerical calculations with far greater speed and accuracy than humans could ever hope to achieve. Computers can also apply and follow rules more consistently and with fewer errors than humans and can process complex mathematical patterns better than humans.

Still, the brain's extraordinary capabilities will probably not be mimicked completely by computers at any time in the near future (Sternberg, 2017). For example, although a computer can improve its ability to recognize patterns or use rules of thumb to make decisions, it does not have the means to develop new learning goals. Furthermore, the human mind is aware of itself; the computer is not. Indeed, no computer is likely to approach the richness of human consciousness.

Nonetheless, the computer's role in cognitive psychology continues to expand. An entire scientific field called **artificial intelligence (AI)** focuses on creating machines capable of performing activities that require intelligence when they are done by people (Flint, Piotrkowicz, & Watts, 2021; Wall & Krummel, 2020). And a newly emerging field called *developmental robotics* is using robots in examining various developmental topics and issues such as motor development, perceptual development, information processing, and language development (Giuffre & others, 2021; Kerzel & others, 2020). The goal is to build robots that are as much like humans as possible and to learn more about humans in the process (Di Nuovo, 2020; Wu & others, 2021).

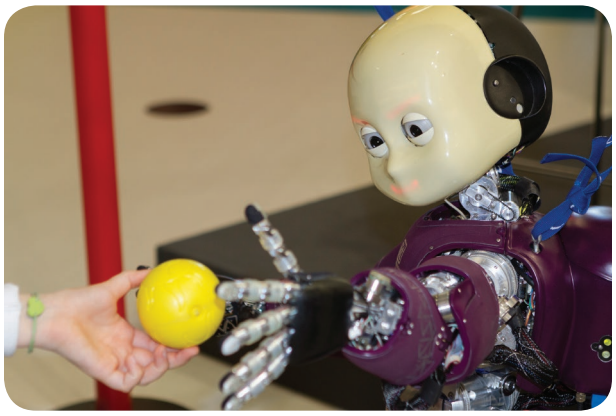
Effective information processing involves attention, memory, and thinking (Siegler & Alibali, 2020). Figure 2 is a basic, simplified representation of how information processing works; it omits a great deal and does not indicate the many routes that the flow of information takes. For example, the processes may overlap and not always go in the left-to-right direction indicated in the figure. A number of different processes may be involved in the way memory functions in processing information. The purpose of the model is to help you to begin thinking in a general way about how people process information. In subsequent sections, we consider details about the way people process information and how information processing changes throughout the life span.

artificial intelligence (AI) Scientific field that focuses on creating machines capable of performing activities that require intelligence when they are done by people.

encoding The process by which information gets into memory.

automaticity The ability to process information with little or no effort.

strategy construction Creation of new procedures for processing information.



The humanoid robot iCub was created by the Italian Institute of Technology to study aspects of children's development such as perception, cognition, and motor development. In this photo, the robot (the size of a 3.5-year-old child) is catching a ball. This robot is being used by more than 20 laboratories worldwide and has 53 motors that move the head, arms and hands, waist, and legs. It also can see and hear, as well as having the sense of proprioception (body configuration) and movement (using gyroscopes).
Marco Destefanis/Pacific Press/Sipa USA/Newscom

Robert Siegler (2006, 2017) emphasizes that *mechanisms of change* play especially important roles in the advances children make in cognitive development. According to Siegler, three mechanisms work together to create changes in children's cognitive skills: encoding, automaticity, and strategy construction.

Encoding is the process by which information gets into memory (Davis & others, 2021). Changes in children's cognitive skills depend on increased skill at encoding relevant information and ignoring irrelevant information. For example, to a 4-year-old, an *s* in cursive writing has a shape very different from an *s* that is printed. But a 10-year-old has learned to encode the relevant fact that both are the letter *s* and to ignore the irrelevant differences in shape.

Automaticity refers to the ability to process information with little or no effort. Practice allows children to encode increasing amounts of information automatically. For example, once children have learned to read well, they do not think about each letter in a word as a letter; instead, they encode whole words. Once a task is automatic, it does not require conscious effort. As a result, as information processing becomes more automatic, we can complete tasks more quickly and handle more than one task at a time. If you did not encode words automatically but instead read this page by focusing your attention on each letter in each word, imagine how long it would take you to read it.

Strategy construction is the creation of new procedures for processing information (Graham & others, 2021). For example, children become more proficient readers when they develop the strategy of stopping periodically to take stock of what they have read so far.

FIGURE **2**
A BASIC, SIMPLIFIED MODEL OF INFORMATION PROCESSING.

In addition, Siegler (2006, 2017) argues that children's information processing is characterized by *self-modification*. That is, children learn to apply what they have learned in previous circumstances to adapt their responses to a new situation. Part of this self-modification draws on **metacognition,** which means "thinking about thinking, or knowing about knowing" (Dos Santos Kawata & others, 2021; Pennequin & others, 2020). One example of metacognition is what children know about the best ways to remember what they have read. Do they know that they will be better able to remember what they have read if they can relate it to their own lives in some way? Thus, in Siegler's application of information processing to development, children play an active role in their own cognitive development.

Siegler (2017) also argues that the best way to understand how children learn is to observe them while they are learning. He emphasizes the importance of using the *microgenetic method* to obtain detailed information about processing mechanisms as they are occurring from moment to moment. Siegler concludes that most research methods assess cognitive change indirectly, being more like snapshots than movies. The microgenetic method seeks to discover not just what children know but the cognitive processes involved in how they acquired the knowledge. A typical microgenetic study will be conducted across a series of trials assessed at various times over weeks or months (Miller, 2015). A number of microgenetic studies have focused on specific aspects of academic learning, such as how children learn whole number arithmetic, fractions, and other areas of math (Eaves, Gilmore, & Attridge, 2020). Microgenetic studies also have been used to discover how children learn about a particular issue in science or master a key aspect of learning to read (Siegler & Alibali, 2020).

Strategies also have been the focus of a number of microgenetic investigations (Eaves, Gilmore, & Attridge, 2020). Using the microgenetic approach, researchers have shown that the development of effective strategies takes place gradually. This research has found considerable variability in children's use of strategies, even revealing that they may use an incorrect strategy in solving a math problem for which they had used a correct strategy several trials earlier.

SPEED OF PROCESSING INFORMATION

A limitation on processing information is the speed at which it takes place (Wong & others, 2021). How quickly we process information often influences what we can do with that information. If you are trying to add up in your mind the cost of items you are buying at the grocery store, you need to be able to rapidly compute the sum before you have forgotten the prices of the individual items. Even in infancy, processing speed is important. For example, a longitudinal study found that 5-month-olds who were more efficient in processing information quickly had better high-level cognitive functioning in the preschool years (Cuevas & Bell, 2014). Researchers have devised a number of ways to assess processing speed (Smolak & others, 2021). For example, processing speed can be measured using a reaction-time task in which individuals are asked to push a button as soon as they see a stimulus such as a light. Or individuals might be asked to match numbers with symbols on a computer screen.

metacognition Cognition about cognition, or "knowing about knowing."

Developmental Changes in Speed of Processing

There is abundant evidence that the speed with which cognitive tasks are completed improves dramatically across the childhood years (Ferrer & others, 2013). Processing speed continues to improve in early adolescence (Kuhn, 2009). For example, in one study, 10-year-olds were approximately 1.8 times slower at processing information than young adults on tasks involving reaction time, letter matching, mental rotation, and abstract matching (Hale, 1990). Twelve-year-olds were approximately 1.5 times slower than young adults, but 15-year-olds processed information on the tasks as quickly as the young adults. Also, a study of 8- to 13-year-old children revealed that processing speed increased with age and, further, that the developmental change in processing speed preceded an increase in working memory capacity (Kail, 2007). A study of 9- to 14-year-olds revealed that faster processing speed was linked to a higher level of oral reading fluency (Jacobson & others, 2011). Also, in recent research with 8- to 12-year-olds, faster processing speed was linked to more advanced language abilities, such as expressive vocabulary (Park & others, 2020). And in recent research, slower processing speed was shown by children who had ADHD or a learning disability (Kramer & others, 2020).

Does processing speed decline in adulthood? In K. Warner Schaie's (1996, 2012) Seattle Longitudinal Study, processing speed began declining in middle adulthood. As Figure 3 shows, the slowdown in processing speed continues into late adulthood (Salthouse, 2007, 2019). The

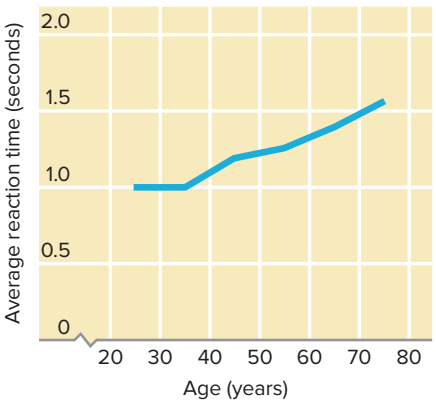


FIGURE **3**

THE RELATION OF AGE TO REACTION TIME. In one study, the average reaction time began to increase in the late thirties, and this decline in processing speed accelerated in the sixties and seventies (Salthouse, 1994). The task used to assess reaction time required individuals to match numbers with symbols on a computer screen.

findings of a research meta-analysis were generally consistent with the graph shown in Figure 3 (Verhaeghen, 2013). Further, in a 20-year longitudinal study of 42- to 97-year-olds, steeper declines in processing speed were linked to increased mortality risk (Aichele, Rabbitt, & Ghisletta, 2015). And in a recent German study of 40- to 85-year-olds, faster processing speed was related to greater life satisfaction (Siedlecki & others, 2020).

Recent research indicates that processing speed is an important indicator of the ability of older adults to continue to effectively drive a vehicle (Bernstein & others, 2021). For example, in a recent study of older adults with a cognitive impairment, slower processing speed was associated with unsafe driving that became worse with increasing age (Hotta & others, 2018). And in a recent study of drivers 70 years of age and older, slower visual processing was linked to higher crash rates (Swain & others, 2021).

Does Processing Speed Matter? How quickly individuals can process information at various points in the life span is linked with their competence in many aspects of cognition (Servant & Evans, 2020). For example, how quickly children can articulate a series of words affects how many words they can remember. Further, a recent study of fifth-graders found that faster processing speed was linked to better reading fluency and comprehension (Gerst & others, 2021).

For some tasks in everyday life, though, speed of processing information may not be important. In addition, the strategies that people learn through experience may compensate for some decline in processing speed with age. In general, however, speed is a very important aspect of processing information (Becker & others, 2021).

2 Attention

LG2 Define attention and outline its developmental changes.

What Is Attention? | Infancy | Childhood and Adolescence | Adulthood

The world holds a lot of information to perceive. Right now, you are perceiving the letters and words that make up this sentence. Now look at your surroundings and focus on something other than this book. After that, curl the toes on your right foot. In each of these circumstances, you engaged in the process of paying attention. What is attention and what effect does it have? How does it change with age?

WHAT IS ATTENTION?

Attention is the focusing of mental resources. Attention improves cognitive processing for many tasks (Bell & Broomell, 2022). At any one time, though, people can pay attention to only a limited amount of information.

attention Focusing of mental resources.

Individuals can allocate their attention in different ways (Richards & Conte, 2021). Psychologists have labeled these types of allocation as selective attention, divided attention, sustained attention, and executive attention.

- **Selective attention** is focusing on a specific aspect of experience that is relevant while ignoring others that are irrelevant. Focusing on one voice among many in a crowded room or a noisy restaurant is an example of selective attention. When you switched your attention to the toes on your right foot, you were engaging in selective attention.
- **Divided attention** involves concentrating on more than one activity at the same time. If you are listening to music or the television while you are reading this chapter, you are engaging in divided attention.
- **Sustained attention** is the ability to maintain attention to a selected stimulus for a prolonged period of time. Sustained attention, which is also called vigilance, involves being on high alert for opportunity or danger as well as paying attention for a length of time (Brown, Panos, & Paul, 2021). In a recent study, sustained attention at 10 months of age was linked to better self-regulation at 18 months of age, even when infants had insensitive mothers (Frick & others, 2018).
- **Executive attention** involves planning actions, allocating attention to goals, detecting and compensating for errors, monitoring progress on tasks, and dealing with novel or difficult circumstances.

This young infant's attention is riveted on the toy in front of him that has just been placed in front of him. *What are some different types of attention?*
Ariel Skelley/Getty Images

INFANCY

How effectively can infants attend to something? Even newborns can detect a contour and fixate on it. Older infants scan patterns more thoroughly (Burack & others, 2020). By 4 months, infants can selectively attend to an object.

Orienting/Investigative Process

Attention in the first year of life is dominated by an *orienting/investigative process* (Gattis & others, 2020; Tham & others, 2021). This process involves directing attention to potentially important locations in the environment (that is, *where*) and recognizing objects and their features (such as color and form) (that is, *what*). From 3 to 9 months of age, infants gradually become able to deploy their attention more flexibly and quickly.

Habituation and Dishabituation

Closely linked with attention are the processes of habituation and dishabituation (Wang & Feigenson, 2021). If you say the same word or show the same toy to a baby several times in a row, the baby usually pays less attention to it each time. This is *habituation*—decreased responsiveness to a stimulus after repeated presentations of the stimulus. *Dishabituation* is the recovery of responsiveness after a change in stimulation.

Infants' attention is often linked to novelty and habituation (Naghashan & others, 2021). When an object becomes familiar, attention becomes shorter, making infants more vulnerable to distraction.

Habituation provides a useful tool for assessing what infants can see, hear, smell, taste, and experience through touch. When infants habituate to one object, and thus it becomes familiar, they will then tend to look at an unfamiliar object, which shows they can distinguish between the objects.

Knowing about habituation and dishabituation can help parents interact effectively with infants. Infants respond to changes in stimulation. Wise parents sense when an infant shows an interest and realize that they may have to repeat something many times for the infant to process information. But if the stimulation is repeated often, the infant stops responding to the parent. In parent-infant interaction, it is important for parents to do novel things and to repeat them often until the infant stops responding. The parent stops or changes behaviors when the infant redirects his or her attention (Rosenblith, 1992).

selective attention Focusing on a specific aspect of experience that is relevant while ignoring others that are irrelevant.

divided attention Concentrating on more than one activity at the same time.

sustained attention The ability to maintain attention to a selected stimulus for a prolonged period of time.

executive attention Cognitive process involving planning actions, allocating attention to goals, detecting and compensating for errors, monitoring progress on tasks, and dealing with novel or difficult circumstances.

A mother and her infant son engaging in joint attention. What about this photograph tells you that joint attention is occurring? *Why is joint attention an important aspect of infant development?*
XiXinXing/age fotostock

Joint Attention Another type of attention that is an important aspect of infant development is **joint attention,** which involves two or more individuals focusing on the same object or event (Piazza & others, 2020). Joint attention requires (1) an ability to track another's behavior, such as following the other person's gaze; (2) one person directing another's attention; and (3) reciprocal interaction. Early in infancy, joint attention usually involves a caregiver pointing or using words to direct an infant's attention. Emerging forms of joint attention may occur as early as midway through the first year, but it is not until toward the end of the first year that joint attention skills are frequently observed (Kawai & others, 2010). Research indicates that joint attention especially improves between 9 and 12 months of age (Boyer, Harding, & Bertenthal, 2020). In a study conducted by Rechele Brooks and Andrew Meltzoff (2005), at 10 to 11 months of age infants first began engaging in "gaze following," looking where another person has just looked (see Figure 4). And by their first birthday, infants have begun to direct adults' attention to objects that capture their interest (Heimann & others, 2006). In one study, the extent to which 9-month-old infants engaged in joint attention was linked to their long-term memory (a one-week delay), possibly because joint attention enhances the relevance of attended items and improves encoding (Kopp & Lindenberger, 2012).

Joint attention plays important roles in many aspects of infant development and considerably increases infants' ability to learn from other people (Piazza & others, 2020). Nowhere is this more apparent than in observations of interchanges between caregivers and infants as infants are learning language (Pablo, Murillo, & Romero, 2020). For example, a parent might point to a toy and say "ball." When caregivers and infants frequently engage in joint attention, infants say their first word earlier and develop a larger vocabulary (Mastin & Vogt, 2016). In a recent study, both joint attention and sustained attention at 9 months predicted vocabulary size at 12 and 15 months, but sustained attention was a stronger predictor of vocabulary size (Yu, Suanda, & Smith, 2019). Researchers also have found that joint attention is linked to better sustained attention (Yu & Smith, 2016), memory (Kopp & Lindenberger, 2011), self-regulation (Brandes-Aitken & others, 2019), and executive function (Gueron-Sela & others, 2018). In a recent study, joint attention was a key factor in linking positive caregiving with executive function in infants in low-income families (Brandes-Aiken & others, 2020). And in a recent study of 8- to 18-month-olds, infants in higher-SES families responded to more sophisticated cues for joint attention than infants from lower-SES families (Reilly & others, 2021).

When joint attention is impaired, the deficit often is linked developmental problems. For example, a recent study found that impaired joint attention at 12 months of age is linked to subsequent diagnosis of autism spectrum disorder and language delay in 3-year-old children (Franchini & others, 2019).

joint attention Focus by individuals on the same object or event; requires an ability to track another's behavior, one individual to direct another's attention, and reciprocal interaction.

FIGURE 4

GAZE FOLLOWING IN INFANCY. Researcher Rechele Brooks shifts her eyes from the infant to a toy in the foreground (*a*). The infant then follows her eye movement to the toy (*b*). Brooks and colleague Andrew Meltzoff (2005) found that infants begin to engage in this kind of behavior, called "gaze following," at 10 to 11 months of age. Why might gaze following be an important accomplishment for an infant?
(*both*): Dr. Andrew Meltzoff, From: Meltzoff et al., Science, 2009, 325, 284–288

CHILDHOOD AND ADOLESCENCE

The child's ability to pay attention improves significantly during the preschool years (Posner & Rothbart, 2018). Toddlers wander around, shift attention from one activity to another, and seem to spend little time focusing on any one object or event. By comparison, the preschool child might be observed watching television for a half-hour. However, one research study revealed that television watching and video game playing were both linked to attention problems in children (Swing & others, 2010).

Young children especially make advances in two aspects of attention—executive attention and sustained attention. In a recent study, children's executive attention was a good predictor of their self-regulation (Tiego & others, 2020). Also, research indicates that although older children and adolescents show increases in vigilance, it is during the preschool years that individuals show the greatest increase in vigilance (Rueda & Posner, 2013).

Mary Rothbart and Maria Gartstein (2008, p. 332) described why advances in executive and sustained attention are so important in early childhood:

> The development of the . . . executive attention system supports the rapid increases in effortful control in the toddler and preschool years. Increases in attention are due, in part, to advances in comprehension and language development. As children are better able to understand their environment, this increased appreciation of their surroundings helps them to sustain attention for longer periods of time.

In at least two ways, however, the preschool child's control of attention is still deficient:

- *Salient versus relevant dimensions*. Preschool children are likely to pay attention to stimuli that stand out, or are salient, even when those stimuli are not relevant to solving a problem or performing a task. For example, if a flashy, attractive clown presents the directions for solving a problem, preschool children are likely to pay more attention to the clown than to the directions. After the age of 6 or 7, children attend more efficiently to the dimensions of the task that are relevant, such as the directions for solving a problem. This change reflects a shift to cognitive control of attention, so that children act less impulsively and reflect more.
- *Planfulness*. Although in general young children's planning improves as part of advances in executive attention, when experimenters ask children to judge whether two complex pictures are the same, preschool children tend to use a haphazard comparison strategy, not examining all of the details before making a judgment. By comparison, elementary-school-age children are more likely to systematically compare the details across the pictures, one detail at a time (Vurpillot, 1968).

In Central European countries such as Hungary, kindergarten children participate in exercises designed to improve their attention (Mills & Mills, 2000; Posner & Rothbart, 2007). For example, in one eye-contact exercise, the teacher sits in the center of a circle of children, and each child is required to catch the teacher's eye before being permitted to leave the group. In other exercises created to improve attention, teachers have children participate in stop-go activities during which they have to listen for a specific signal, such as a drumbeat or an exact number of rhythmic beats, before stopping the activity.

Computer exercises also have been developed to improve children's attention (Rueda & Posner, 2013). For example, one study revealed that five days of computer exercises that involved learning how to use a joystick, draw upon working memory, and resolve conflicts improved the attention of 4- to 6-year-old children (Rueda, Posner, & Rothbart, 2005). In one of the computer games, young children have to move a joystick to keep a cat on the grass and out of the mud, and in another they help a cat find a duck in a pond. Also, in a recent study of 4- to 5-year-olds, two weeks of training on action-like mini games improved the young children's visuo-spatial attention skills (Nava, Focker, & Gori, 2020). Although these games are not commercially available, further information about computer exercises for improving children's attention is available at www.teach-the-brain.org/learn/attention/index.

How might good attentional skills benefit children's development? Preschool children's ability to control and sustain their attention is related to school readiness (Rothbart, 2011). For example, a study of more than 1,000 children revealed that their ability to sustain their attention at 54 months of age was linked to their school readiness (which included achievement and language skills) (NICHD Early Child Care Research Network, 2005). Further, in another

study the ability to focus attention better at age 5 was linked to a higher level of school achievement at age 9 (Razza, Martin, & Brooks-Gunn, 2012). And in a recent study of 4- to 6-year-olds, better attention was linked to improved math skills (Cueli & others, 2020). Also, attention to relevant information increases steadily during the elementary and secondary school years (Davidson, 1996). Processing of irrelevant information decreases in adolescence.

Another important aspect of attention is the ability to shift it from one activity to another as needed. For example, writing a good story requires shifting attention among the competing tasks of forming letters, composing grammar, structuring paragraphs, and conveying the story as a whole. Older children and adolescents are better than younger children at tasks that require shifting attention.

One trend involving divided attention is adolescents' multitasking, which in some cases involves not just dividing attention between two activities, but even three or more. A major factor that encourages multitasking is the availability of multiple electronic media. Many adolescents have a range of electronic media at their disposal. It is not unusual for adolescents to divide their attention by working on homework while engaging in an instant messaging conversation, surfing the Web, and listening to an iTunes playlist. And a national survey revealed that 50 percent of adolescents made and answered phone calls while driving, and 13 percent (approximately 1.7 million) wrote and/or read text messages while driving (Allstate Foundation, 2005). A recent analysis of research studies concluded that heavy media multitasking in adolescence is linked to poorer memory, increased impulsivity, and reduced volume in the brain's cerebral cortex (Uncapher & others, 2017). In addition, a recent study found that heavier media multitasking was linked to attention lapses and more forgetting (Madore & others, 2020).

Further, another recent study indicated that heavy multimedia multitaskers were less likely than light multimedia multitaskers to delay gratification and more likely to endorse intuitive but wrong answers on a reflective cognitive task (Schutten, Stokes, and Arnell, 2017).

Thus, in many circumstances multitasking is not beneficial (Lopez, Heatherton, & Wagner, 2020). If the key task is at all complex and challenging, such as trying to figure out how to solve a homework problem, multitasking considerably reduces attention to the key task (Myers, 2008).

Controlling attention is an important aspect of learning and thinking in adolescence and emerging adulthood (Brooker & others, 2020). Distractions that can interfere with attention in adolescence and emerging adulthood come from the external environment (other students talking while the student is trying to listen to a lecture, or the student turning on a laptop or tablet PC during a lecture and looking at a new friend request on Facebook, for example) or intrusive distractions from competing thoughts in the individual's mind. Self-oriented thoughts, such as worrying, self-doubt, and intense, emotionally laden thoughts may especially interfere with focusing attention on thinking tasks.

developmental **connection**
Media/Screen Time
In a survey, when media multitasking was taken into account, 11- to 14-year-olds spent nearly 12 hours a day using media. Connect to "Peers and the Sociocultural World."

ADULTHOOD

What happens to attention in adulthood? Attentional skills are often excellent in early adulthood and, of course, the discussion of divided attention and multitasking applies to many adults as well as adolescents. However, in many contexts older adults may not be able to focus on relevant information as effectively as younger adults (Robertson & Dockree, 2020). Older adults have more difficulty in attention that involves various aspects of driving, distraction, selective attention, and complex vigilance tasks. Let's examine research that documents declines in older adults' attention in these areas.

Consider a study that examined the role that visual attention, involving search, selection, and switching, played in the performance of older adult drivers (Richardson & Marottoli, 2003). Thirty-five community-dwelling drivers aged 72 and older (mean age, 80) underwent an on-road driving evaluation involving parking lot maneuvers and urban, suburban, and highway driving. They were also given tests of visual attention. The worse their driving was, the lower were their scores on visual attention tests. Yielding right of way and negotiating safe turns or merges were especially related to visual attention.

developmental **connection**
Perception
Researchers study declines in the perceptual skills involved in older adults' driving performance. Connect to "Motor, Sensory, and Perceptual Development."

Might training sessions to improve older adults' attention be beneficial? One study revealed that older adults who participated in 20 one-hour video game training sessions with a commercially available program (Lumosity) showed a significant reduction in distraction and increased alertness (Mayas & others, 2014). The Lumosity program sessions focus on problem solving, mental calculation, working memory, and attention. Also, in a recent study, executive attention training, which involves attention directed at higher-level thinking activities, improved the selective attention of older adults (Yang & others, 2019). And a recent research review of game-based training and cognition concluded that the training improved selective attention in older adults (Wang & others, 2021).

Older adults tend to be less adept at exercising selective attention—focusing on a specific aspect of experience while ignoring others—than younger adults are (Loaiza & Souza, 2019). These age differences are minimal if the task involves a simple search (such as determining whether a target item is present on a computer screen) or if individuals have practiced the task (Kramer & Madden, 2008). As the demands on attention increase, however, the performance of older adults declines (Kramer & Madden, 2008).

How well do older adults perform on tasks that involve vigilance? On tests of simple vigilance and sustained attention, older adults usually perform as well as younger adults. For example, one study revealed that sustained attention increased in early adulthood but remained unchanged thereafter through 77 years of age (Carriere & others, 2010). However, on complex vigilance tasks, older adults' performance usually drops (Lufi & Haimov, 2019).

Possibly, though, older adults' experience and wisdom might be able to offset some of their declines in vigilance. For example, consider how many young people focus intently on their smartphone rather than looking at traffic when walking across a dangerous intersection.

What are some developmental changes in attention in adulthood?

3 Memory

LG3 Describe what memory is and how it changes through the life span.

What Is Memory? | Infancy | Childhood | Adulthood

Twentieth-century American playwright Tennessee Williams once commented that life is all memory except for that one present moment that goes by so quickly that you can hardly catch it going. But just what is memory?

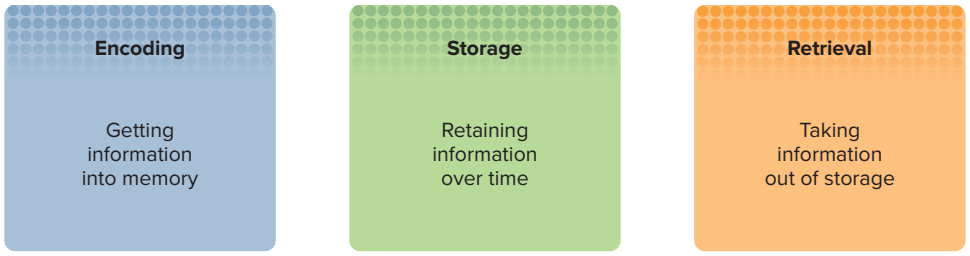
WHAT IS MEMORY?

Memory is the retention of information over time. Without memory you would not be able to connect what happened to you yesterday with what is going on in your life today. Human memory is truly remarkable when you think of how much information we put into our

memory Retention of information over time.

FIGURE 5

PROCESSING INFORMATION IN MEMORY. As you read about the many aspects of memory in this chapter, think about the organization of memory in terms of these three main activities.



developmental **connection**

Gender

Gender schema theory emphasizes children's gender schemas that organize the world in terms of male and female. Connect to "Gender and Sexuality."

memories and how much we must retrieve to perform all of life's activities. However, human memory has imperfections that will be discussed shortly.

Processes of Memory Researchers study how information is initially placed in or encoded into memory, how it is retained or stored after being encoded, and how it is found or retrieved for a certain purpose later (see Figure 5). Encoding, storage, and retrieval are the basic processes required for memory. Failures can occur in any of these processes. Some part of an event might not be encoded, the mental representation of the event might not be stored, or even if the memory exists, the information may not be retrievable.

Constructing Memory Memories may be inaccurate for a number of reasons. Memory is not like a tape recorder or a camera or computer flash drive. People construct and reconstruct their memories (Schacter, 2021). According to **schema theory,** people mold memories to fit information that already exists in their minds. This process is guided by **schemas,** which are mental frameworks that organize concepts and information. Schemas influence the way people encode, make inferences about, and retrieve information (Rubinova & others, 2021). Often when we retrieve information, we fill in gaps.

We have schemas for all sorts of information. If a teacher tells your class a story about two men and two women who were involved in a train crash in France, students won't remember every detail of the story and will reconstruct the story with their own particular stamp on it. One student might reconstruct the story by saying that the people died in a plane crash, another might describe three men and three women, another might say the crash was in Germany, and so on. Such reconstruction and distortion are nowhere more apparent than in clashing testimony given by eyewitnesses at trials.

In sum, schema theory accurately predicts that people don't store and retrieve bits of data in computer-like fashion (Zacks, Bezdek, & Cunningham, 2021). We reconstruct the past rather than take an exact photograph of it, and the mind can distort an event as it encodes and stores impressions of it (Pudhiyidath & others, 2020).

schema theory Theory stating that people mold memories to fit information that already exists in their minds.

schemas Mental frameworks that organize concepts and information.

FIGURE 6

THE TECHNIQUE USED IN ROVEE-COLLIER'S INVESTIGATION OF INFANT MEMORY. In Rovee-Collier's experiment, operant conditioning was used to demonstrate that infants as young as 2½ months of age can retain information from the experience of being conditioned.
Courtesy of Dr. Carolyn Rovee-Collier

INFANCY

Popular child-rearing expert Penelope Leach (1990) told parents that 6- to 8-month-old babies cannot hold a picture of their mother or father in their mind. However, child development researchers have revealed that even newborns show a limited type of memory.

First Memories Carolyn Rovee-Collier (1987, 2007) has conducted research that demonstrates infants can remember perceptual-motor information. In a characteristic experiment, she places a baby in a crib underneath an elaborate mobile and ties one end of a ribbon to the baby's ankle and the other end to the mobile. The baby kicks and makes the mobile move (see Figure 6). Weeks later, the baby is returned to the crib, but its foot is not tied to the mobile. The baby kicks, apparently trying to make the mobile move. However, if the mobile's makeup is changed even slightly, the baby doesn't kick. If the mobile is then restored to being exactly as it was when the baby's ankle was tied to it, the baby will begin kicking again. According to Rovee-Collier, even at 2½ months the baby's memory is detailed.

How well can infants remember? Some researchers such as Rovee-Collier (2007; Rovee-Collier & Barr, 2010) have concluded that infants as young as 2 to 6 months of age can remember some experiences until they are 1½ to 2 years of age. However, critics such as Jean Mandler (2000), a leading expert on infant cognition, argue that the infants in Rovee-Collier's experiments

are displaying only implicit memory. **Implicit memory** refers to memory without conscious recollection—memories of skills and routine procedures that are performed automatically. In contrast, **explicit memory** refers to the conscious recollection of facts and experiences.

When people think about memory, they are usually referring to explicit memory. Most researchers find that babies do not show explicit memory until the second half of the first year (Bauer & Fivush, 2014). Then explicit memory improves substantially during the second year of life (Lukowski & Bauer, 2014). In one longitudinal study, infants were assessed several times during their second year (Bauer & others, 2000). Older infants showed more accurate memory and required fewer prompts to demonstrate their memory than younger infants did. Researchers have documented that 6-month-olds can remember information for 24 hours, but by 20 months of age infants can remember information they encountered 12 months earlier.

In sum, most of young infants' conscious memories are fragile and short-lived, except for memory of perceptual-motor actions, which can be substantial (Mandler, 2000). Conscious memories improve across the second year of life (Hayne & Herbert, 2021).

What changes in the brain are linked to infants' memory development? From about 6 to 12 months of age, the maturation of the hippocampus and the surrounding cerebral cortex, especially the frontal lobes, makes the emergence of explicit memory possible (Mullally & Maguire, 2014) (see Figure 7). Explicit memory continues to improve during the second year as these brain structures further mature and connections between them increase. Less is known about the areas of the brain involved in implicit memory in infancy.

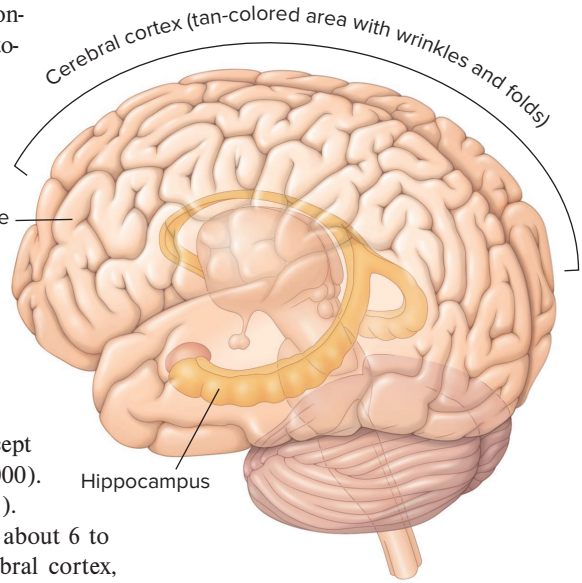


FIGURE **7**

KEY BRAIN STRUCTURES INVOLVED IN EXPLICIT MEMORY DEVELOPMENT IN INFANCY.

Infantile Amnesia Do you remember your third birthday party? Probably not. Most adults can remember little if anything from their first three years of life (Bauer, 2015). This is called infantile, or childhood, amnesia. The few reported adult memories of life at age 2 or 3 are at best very sketchy (Li, Callaghan, & Richardson, 2014).

Patricia Bauer and her colleagues (Larkina, Merrill, & Bauer, 2017) recently have been studying when infantile amnesia begins to occur. In one study, children's memory for events that occurred at 3 years of age was periodically assessed through age 9 (Bauer & Larkina, 2014). By 8 to 9 years of age, children's memory of events that occurred at 3 years of age began to significantly fade away. Also, in a longitudinal study from 1.5 years to 16 years of age, the age of first memory increased from 40 months at age 12 to 52 months at age 16 (Reese & Robertson, 2019). In this study, individual differences in age of first memory were linked to the extent to which mothers engaged in elaborative reminiscing. In Bauer's (2015) view, the processes that account for these developmental changes are early, gradual development of the ability to form, retain, and later retrieve memories of personally relevant past events followed by an accelerated rate of forgetting in childhood.

What causes infantile amnesia? One reason for the difficulty older children and adults have in recalling events from their infancy is immaturity of two regions of the brain—the hippocampus and prefrontal cortex—which play key roles in memory for events (Josselyn & Frankland, 2012).

CHILDHOOD

Children's memory improves considerably after infancy (Howard, Riggins, & Woodward, 2020; Saragosa-Harris & others, 2021). What are some of the significant strides in memory as children grow older? Developmental progress includes improvements in different types of memory, as well as the use of strategies.

Short-Term and Working Memory When people talk about memory, they are usually referring to **long-term memory,** which is relatively permanent and unlimited. When you remember the types of games you enjoyed playing as a child, details of your first date, or characteristics of the life-span perspective, you are drawing on your long-term memory. But when you remember the word you just read, you are using short-term memory.

Short-term memory involves retaining information for up to 30 seconds without rehearsal (repetition) of the information. Using rehearsal, individuals can keep information in short-term memory longer (Yen, 2008).

implicit memory Memory without conscious recollection—memory of skills and routine procedures that are performed automatically.

explicit memory Conscious memory of facts and experiences.

long-term memory A relatively permanent and unlimited type of memory.

short-term memory Retention of information for up to 15 to 30 seconds, without rehearsal of the information. Using rehearsal, individuals can keep the information in short-term memory longer.

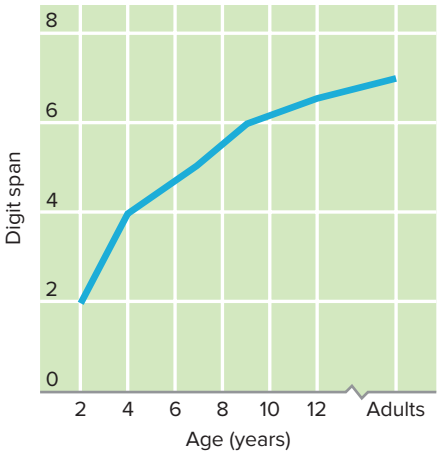

FIGURE 8

DEVELOPMENTAL CHANGES IN MEMORY SPAN. In one study, memory span increased by about three digits from 2 years to 7 years of age (Dempster, 1981). By 12 years of age, memory span had increased on average another one and a half digits.

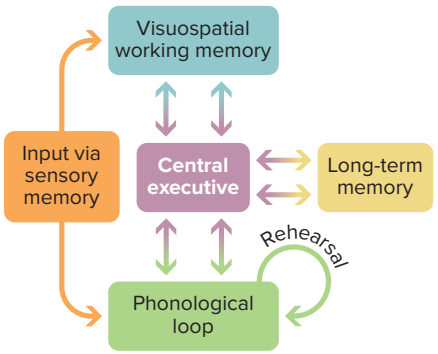

FIGURE 9

WORKING MEMORY. In Baddeley's working memory model, working memory is like a mental workbench where a great deal of information processing is carried out. Working memory consists of three main components. The phonological loop and visuospatial working memory serve as assistants, helping the central executive do its work. Input from sensory memory goes to the phonological loop, where information about speech is stored and rehearsal takes place, and visuospatial working memory, where visual and spatial information, including imagery, are stored. Working memory is a limited-capacity system, and information is stored there for only a brief time. Working memory interacts with long-term memory, using information from long-term memory in its work and transmitting information to long-term memory for longer storage.

working memory A mental "workbench" where individuals manipulate and assemble information when making decisions, solving problems, and comprehending written and spoken language.

Memory Span Unlike long-term memory, short-term memory has a very limited capacity. One method of assessing that capacity is the memory-span task. You simply hear a short list of stimuli—usually digits—presented at a rapid pace (one per second, for example). Then you are asked to repeat the digits.

Research with the memory-span task suggests that short-term memory increases during childhood. For example, in one investigation, memory span increased from about two digits in 2- to 3-year-old children to about five digits in 7-year-old children. Between 7 and 12 years of age, memory span increased by only one and a half digits (Dempster, 1981) (see Figure 8). Keep in mind, though, that individuals have different memory spans.

Why does memory span change with age? Rehearsal of information is important, and older children rehearse the digits more than younger children do. Speed of processing information is important, too, especially the speed with which memory items can be identified. For example, one study tested children on their speed at repeating words presented orally (Case, Kurland, & Goldberg, 1982). Speed of repetition was a powerful predictor of memory span. The children who were able to quickly repeat the presented words were also far more likely to have greater memory spans. Indeed, when the speed of repetition was controlled, the 6-year-olds' memory spans were equal to those of young adults.

Working Memory Short-term memory is like a passive storehouse with shelves to store information until it is moved to long-term memory. In recent years, the more active, dynamic term *working memory* has been used to provide a more comprehensive account of memory storage. Alan Baddeley (2007, 2015, 2018, 2019) defines **working memory** as a kind of mental "workbench" where individuals manipulate and assemble information when they make decisions, solve problems, and comprehend written and spoken language (see Figure 9). Working memory involves bringing information to mind and mentally working with or updating it, as when you link one idea to another and relate what you are reading now to something you read earlier. Recent research confirms that working memory is a foundational cognitive activity, with the frontoparietal brain network playing a key role in its development (Rosenberg & others, 2020).

Working memory develops slowly. Even by 8 years of age, children can only hold in memory half the items that adults can remember (Kharitonova, Winter, & Sheridan, 2015). Working memory is linked to many aspects of children's development (Vernucci & others, 2020). For example, children who have better working memory are more advanced in language comprehension, math skills, problem solving, and reasoning than their counterparts with less effective working memory (Ding & others, 2019). In a recent study of preschool children, better working memory was linked to improved number knowledge skills (Traverso & others, 2021). In another study, children's verbal working memory was linked to these aspects of both first and second language learners: morphology, syntax, and grammar (Verhagen & Leseman, 2016). In addition, recent research with first- to third-graders indicated that working memory improvement predicted math problem-solving growth in emergent bilingual children (Swanson, Arizemendi, & Li, 2021). Further, recent research indicates that children with ADHD have working memory deficits (Kofler & others, 2020; Valladares & others, 2021).

Children's Long-Term Memory

In contrast with short-term and working memory, *long-term memory* is a relatively permanent type of memory that stores huge amounts of information for a long time. One aspect of long-term memory that has been extensively studied in children's development is autobiographical memory. Also, there has been considerable interest in children's memory in the courtroom when they are asked for eyewitness testimony. Keep in mind that it is important not to view memory in terms of how children add something to it but rather to underscore how children actively construct their memory (Schacter, 2021).

Autobiographical Memory Memory of significant events and experiences in one's life is called *autobiographical memory* (Haliford & others, 2021). You are engaging in autobiographical memory when you answer questions such as: Who was your first-grade teacher, and what was s/he like? What is the most traumatic event that happened to you as a child?

Earlier we described the phenomenon of infantile amnesia, in which individuals can't remember anything from their first three years of life, and recent research indicating that these memories begin to fade by 8 to 9 years of age.

During the preschool years, young children's memories increasingly take on more autobiographical characteristics (Bauer, 2018). In some areas, such as remembering a story, a

movie, a song, or an interesting event or experience, young children have been shown to have reasonably good memories. From 3 to 5 years of age, they (1) increasingly remember events as occurring at a specific time and location, such as "on my birthday at Chuck E. Cheese's last year" and (2) include more elements that are rich in detail in their narratives (Bauer, 2013). In one study, children went from using four descriptive items per event at 3½ years of age to 12 such items at 6 years of age (Fivush & Haden, 1997). Although the long-term memories of preschoolers can seem to be erratic at times, they can remember a great deal of information if they are given appropriate cues and prompts. Also, a recent study of 3- to 6-year-olds found that the volume of their autobiographical memories was linked to the volume of their self-knowledge (Ross, Hutchison, & Cunningham, 2020).

As children go through middle and late childhood and then adolescence, their autobiographical narratives broaden and become more elaborated (Bauer, 2013). Researchers have found that children develop more detailed, coherent, and evaluative autobiographical memories when their mothers reminisce with them in elaborated and evaluative ways (Fivush, 2010).

Eyewitness Testimony One area in which children's long-term memory is being examined extensively relates to whether young children should be allowed to testify in court (Karni-Visel & others, 2019). Increasingly, young children are being allowed to testify, especially if they are the only witnesses to abuse, a crime, and so forth (Pantell & others, 2017).

Several factors influence the accuracy of a young child's memory (Bruck & Ceci, 1999):

- *There are age differences in children's susceptibility to suggestion*. Preschoolers are much more susceptible to suggestion than are older children and adults (Ceci, Papierno, & Kulkofsky, 2007). For example, preschool children are more susceptible to absorbing misleading or incorrect post-event information (Ghetti & Alexander, 2004). Despite these age differences, there is also concern about the accuracy of older children's recollections of events if they are subjected to suggestive interviews (Ahern, Kowalski, & Lamb, 2018).
- *There are individual differences in susceptibility*. Some preschoolers are highly resistant to interviewers' suggestions, whereas others immediately succumb to the slightest suggestion.
- *Interviewing techniques can produce substantial distortions in children's reports about highly salient events*. Children are suggestible not just about peripheral details but also about the central aspects of an event (Malloy & others, 2012). Their false claims have been found to persist for at least three months (Ornstein, Gordon, & Larus, 1992). Nonetheless, young children are capable of recalling much that is relevant about an event (Goodman, Batterman-Faunce, & Kenney, 1992). When children do accurately recall an event, the interviewer often has a neutral tone, there is limited use of misleading questions, and there is an absence of any motivation for the child to make a false report (Bruck & Ceci, 2013). Also, a recent research review concluded that interviewer support increases children's memory accuracy (Saywitz & others, 2019).

In sum, whether a young child's eyewitness testimony is accurate or not may depend on a number of factors such as the type, number, and intensity of the suggestive techniques the child has experienced (Malloy & Stolzenberg, 2020). It appears that the reliability of young children's reports has as much to do with the skills and motivation of the interviewer as with any natural limitations on young children's memory.

Children's long-term memory improves even more as they move into middle and late childhood. This advance is especially true when they use the strategies that we describe next.

What are some conclusions from research on young children's ability to provide accurate eyewitness testimony?
Buddy Norris/KRT/Newscom

Strategies

Strategies involve the use of mental activities to improve the processing of information (Graham & others, 2021). Rehearsing information and organizing are two typical strategies that older children (and adults) use to remember information more effectively. Rehearsal (repetition) works better for short-term memory. Strategies such as organization, elaborating on the information to be remembered, and making it personally relevant can make long-term memory more effective. Preschool children usually do not use strategies such as rehearsal and organization to remember (Flavell, Miller, & Miller, 2002).

Imagery Creating mental images is another strategy for improving memory (Strachan, Hyett, & McEvoy, 2020). However, using imagery to remember verbal information works better for older children than for younger children (Schneider, 2011).

Elaboration One important strategy is **elaboration,** which involves engaging in more extensive processing of information. When individuals engage in elaboration, their memory benefits (Andrade & Raposo, 2021). Thinking of examples, especially those related to yourself, is an effective way to elaborate information. Thinking about personal associations with information makes the information more meaningful and helps children to remember it. For example, if the word *win* is on a list of words a child is asked to remember, the child might think of the last time she won a bicycle race.

The use of elaboration changes developmentally (Schneider, 2011). Adolescents are more likely than children to use elaboration spontaneously. Elementary school children can be taught to use elaboration strategies on a learning task, but they will be less likely than adolescents to use the strategies on other learning tasks in the future. Nonetheless, verbal elaboration can be an effective strategy even for young elementary school children.

Fuzzy Trace Theory One theory that emphasizes the reconstructive aspects of memory provides an alternative to strategies in explaining developmental changes in children's memory. Proposed by Charles Brainerd and Valerie Reyna (1993, 2004, 2014), **fuzzy trace theory** states that memory is best understood by considering two types of memory representations: (1) verbatim memory trace and (2) gist. Verbatim memory trace consists of the precise details of the information, whereas gist refers to the central idea of the information. When gist is used, fuzzy traces are built up. Although individuals of all ages extract gist, young children tend to store and retrieve verbatim traces. At some point during the early elementary school years, children begin to use gist more and, according to the theory, its use contributes to the improved memory and reasoning of older children because fuzzy traces are more enduring and less likely to be forgotten than verbatim traces (Brainerd & Reyna, 2014).

Knowledge An especially important influence on memory is the knowledge that individuals possess about a specific topic or skill (Ericsson & others, 2018). Knowledge influences what people notice and how they organize, represent, and interpret information. This skill, in turn, affects their ability to remember, reason, and solve problems (Zimmer & Fischer, 2020).

One study found that 10- and 11-year-olds who were experienced chess players were able to remember more information about chess pieces than college students who were not chess players (Chi, 1978) (see Figure 10). In contrast, the college students were able to remember other stimuli better than the children were. Thus, the children's expertise in chess gave them superior memories, but only in chess. A key reason the child chess experts did better at this activity was their ability to organize (chunk) the chess pieces into meaningful subgroups based on their understanding of chess.

elaboration Engagement in more extensive processing of information, benefiting memory.

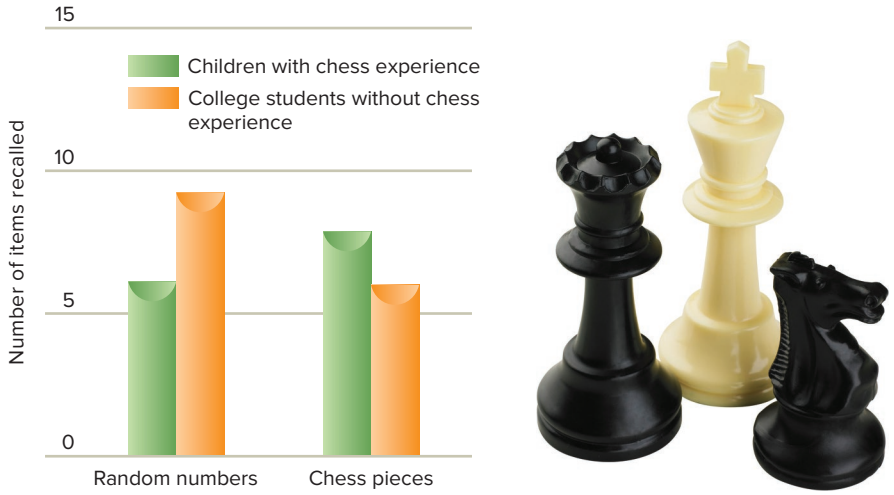
fuzzy trace theory States that memory is best understood by considering two types of memory representations: (1) verbatim memory trace and (2) gist.

Teaching Strategies So far we have described several important strategies adults can adopt when guiding children to remember information more effectively over the long term. These strategies include showing children how to organize information, how to elaborate the information, and how to develop images of the information. Another good strategy is to

FIGURE **10**

MEMORY FOR NUMBERS AND CHESS PIECES.

Tetra Images/Alamy Stock Photo



encourage children to understand the material that needs to be remembered rather than rotely memorizing it. Two other strategies adults can use to guide children's retention of memory have been proposed:

- *Repeat with variation on the instructional information, and link early and often.* These are memory development research expert Patricia Bauer's (2009) recommendations to improve children's consolidation and reconsolidation of the information they are learning. Variations on a lesson theme increase the number of associations in memory storage, and linking expands the network of associations in memory storage; both strategies expand the routes for retrieving information from storage.
- *Embed memory-relevant language when instructing children*. Teachers vary considerably in how much they use memory-relevant language that encourages students to remember information. In research that involved extensive observations of a number of first-grade teachers in the classroom, Peter Ornstein and his colleagues (Ornstein, Coffman, & Grammer, 2007; Ornstein, Haden, & Coffman, 2010) found that in the time segments observed, the teachers rarely used strategy suggestions or metacognitive (thinking about thinking) questions. In this research, when lower-achieving students were placed in classrooms in which teachers were categorized as "high-mnemonic teachers" who frequently embedded memory-relevant information in their teaching, the students' achievement increased (Ornstein, Coffman, & Grammer, 2007).

ADULTHOOD

Memory changes during the adult years, but different aspects of memory are affected differently as adults age (Duarte & Dulas, 2020). Let's look first at working memory.

Working Memory Working memory is an important process and resource for effective memory (Aziz & others, 2021). Remember that working memory is like a mental "workbench" that allows us to manipulate and assemble information (Baddeley, 2019). Researchers have consistently found declines in working memory during late adulthood (Cansino & others, 2020a). One study revealed that working memory continued to decline from 65 to 89 years of age (Elliott & others, 2011). Another study found that visually encoded working memory was linked to older adults' mobility (Kawagoe & Sekiyama, 2014).

Is plasticity part of the working memory of older adults? Researchers have found that older adults' working memory can be improved through training (Brum & others, 2020). In one study, aerobic endurance was linked to better working memory in older adults (Zettel-Watson & others, 2017). Another study revealed that imagery strategy training improved older adults' working memory (Borella & others, 2017). Thus, there appears to be some plasticity in the working memory of older adults (Oh & others, 2018). However, a study of young, middle-aged, and older adults found that the working memory of all age groups improved with training, but the older adults showed less improvement with training than the younger adults did (Rhodes & Katz, 2017). Also, a recent study by Lisandra Mendoza and her colleagues (2021) revealed that Latinx older adults who were more acculturated (better adjusted to their new culture in the United States, for example) had better working memory than their less acculturated counterparts. Why might this occur? The factors involved might include the influence of acculturation in securing cognitively engaging employment and social support. Also, less acculturation might affect how research participants perform on a cognitive task designed for non-immigrant participants.

Explanations of the decline in working memory in older adults focus on their less efficient inhibition in preventing irrelevant information from entering working memory and their increased distractibility (Hasher & Campbell, 2020). Declines in processing speed (Salthouse, 2019) and attention (Loaiza & Souza, 2019) in middle and late adulthood may play a role in working memory decline as well.

Explicit and Implicit Memory Long-term memory systems include explicit and implicit memory. Recall that *explicit memory* refers to conscious memories of facts and experiences. Explicit memory is also sometimes called *declarative memory*. Examples of explicit memory include being at a grocery store and remembering that you want to buy something or being able to recall the plot of a movie you have seen. There are two main types of explicit memory: (1) episodic memory and (2) semantic memory.

Recall that *implicit memory* refers to memory of skills and routine procedures that are performed automatically. (Implicit memory is sometimes referred to as procedural memory.) Examples of implicit memory include unconsciously remembering how to drive a car, swing a golf club, or type on a computer keyboard.

Explicit Memory and Aging Explicit memory can be subdivided into episodic memory and semantic memory. **Episodic memory** is retention of information about the where and when of life's happenings. For example, what color were the walls in your bedroom when you were a child? What did you eat for breakfast this morning? What were you doing when you heard that the World Trade Center had been destroyed on 9/11/2001? Younger adults have better episodic memory than older adults have, both for real and imagined events (Duarte & Dulas, 2020). One study found that episodic memory performance predicted which individuals would develop dementia 10 years prior to clinical diagnosis of the disease (Boraxbekk & others, 2015). In another study, a mindfulness training program was effective in improving episodic memory recall in older adults (Banducci & others, 2017).

Autobiographical memories are stored as episodic memories (Wank & others, 2020). A recent study found that age-related decline in episodic memory impairs access to specific autobiographical events and the details involved (Peters, Fan, & Sheldon, 2019). A robust finding in autobiographical memory is called the *reminiscence bump,* in which adults remember more events from the second and third decades of their lives than from other decades (Kowalski & McCord, 2020; Liao, Bluck, & Gluck, 2021). The "bump" is found more for positive than negative life events. Also, a recent study of 60- to 88-year-olds revealed that the first-time experience of a memory, the importance of the memory, and the emotional salience of the memory were associated with the reminiscence bump (Wolf & Zimprich, 2020).

Semantic Memory **Semantic memory** is a person's knowledge about the world. It includes a person's fields of expertise (such as knowledge of chess for a skilled chess player); general academic knowledge of the sort learned in school (such as knowledge of geometry); and "everyday knowledge" about meanings of words, famous individuals, important places, and common things (such as who Nelson Mandela and Mother Teresa were). However, the ability to retrieve very specific information (such as names) usually declines in older adults (Hoffman & Morcom, 2018). For the most part, episodic memory declines more than semantic memory in older adults (Jarjat, Portrat, & Hot, 2020).

episodic memory Retention of information about the where and when of life's happenings.

semantic memory A person's knowledge about the world, including fields of expertise, general academic knowledge, and "everyday knowledge" about meanings of words, names of famous individuals, important places, and common things.

Although older adults often take longer to retrieve semantic information, usually they can ultimately retrieve it. As shown in Figure 11, semantic memory continues to increase through the fifties, showing little decline even through the sixties (Ronnlund & others, 2005). Figure 11 also shows how the gap between semantic and episodic memory widens during middle and late adulthood. In one study, after almost five decades adults identified pictures of their high school classmates with better than 70 percent accuracy (Bahrick, Bahrick, & Wittlinger, 1975). How well do most adults remember the actual subjects they learned in high school, however? In the *Connecting with Research* interlude, we focus on another study that examined the developmental aspects of semantic memory.

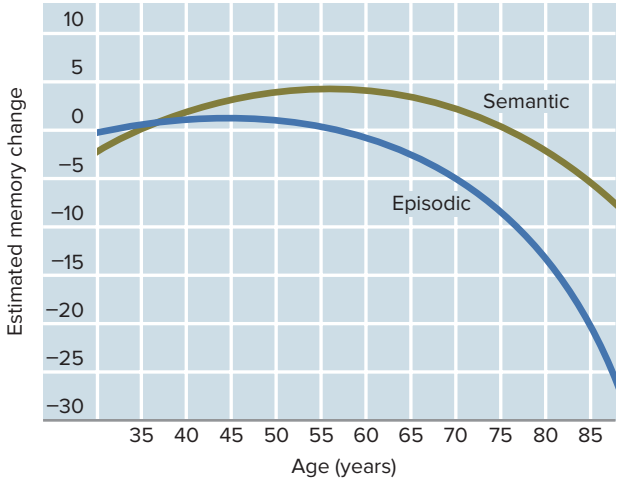


FIGURE **11**
CHANGES IN EPISODIC AND SEMANTIC MEMORY IN ADULTHOOD.

Although many aspects of semantic memory are reasonably well preserved in late adulthood, a common memory problem for older adults is the *tip-of-the-tongue (TOT) phenomenon*, in which individuals can't quite retrieve familiar information but have the feeling that they should be able to retrieve it. Researchers have found that older adults are more likely than younger adults to experience TOT states (Campos-Magdaleno & others, 2020).

Implicit Memory and Aging Implicit memory is less likely than explicit memory to be adversely affected by aging (Davis & others, 2021). Thus, older adults are more likely to forget which items they wanted to buy at the grocery store (unless they wrote them down on a list and took it with them) than they are to forget how to drive a car. Their processing speed may be slower when driving the car, but they can remember how to do it. Further, Alzheimer disease is characterized by the early onset of explicit memory deficits, while implicit memory is not affected until later stages of the disease (Boccia, Silveri, & Guariglia, 2014). Also, in a recent study, research with older adults found that those with mild cognitive impairment showed slower reaction time but had largely preserved implicit memory (Hong & others, 2020).

How Well Do Adults Remember What They Learned in High School and College Spanish?

Harry Bahrick

Key Points:

- older adults' memory
- high school and college Spanish instruction classes
- excellent memory of what was learned 50 years ago

When older adults are assessed for what they learned in high school or college, researchers find neither great durability in memory nor huge deterioration (Salthouse, 1991). In one study, non-Latinx adults of various ages in the United States were tested to determine how much Spanish they remembered from classes they had taken in high school or college (Bahrick, 1984). The individuals chosen for the study had used Spanish very little since they initially learned it in high school or college. Not surprisingly, young adults who had taken Spanish classes within the last three years remembered their Spanish best. After that, the deterioration in memory was very gradual (see Figure 12). For example, older adults who had studied Spanish 50 years earlier remembered about 80 percent of what young adults did who had studied it in the last three years! The most important factor in the adults' memory of Spanish was not how long ago they had studied it but how well they had initially learned it—those who got an A in Spanish 50 years earlier remembered more Spanish than those who got a C when taking Spanish only one year earlier.

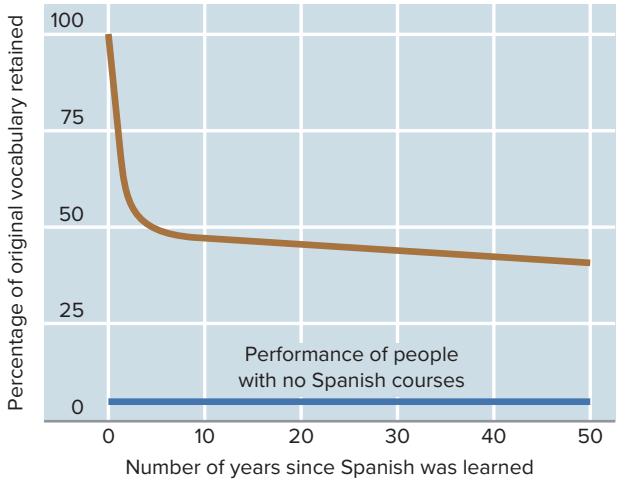

FIGURE **12**

MEMORY FOR SPANISH AS A FUNCTION OF AGE SINCE SPANISH WAS LEARNED. An initial steep drop occurred over about a three-year period in remembering the vocabulary learned in Spanish classes. However, there was little dropoff in memory for Spanish vocabulary from three years after taking Spanish classes to 50 years after taking them. Even 50 years after taking Spanish classes, individuals still remembered almost 50 percent of the vocabulary.

What are some of the implications of the research on what adults remember from high school for improving teaching methods in U.S. schools?

Source Memory

Source memory is the ability to remember where one learned something. The contexts of source memory might be the physical setting, emotions experienced, or the identity of the speaker. Failures of source memory increase with age during the adult years (Cansino & others, 2020b). Such failures can be embarrassing, as when an older adult forgets who told a joke and retells it to the source. However, researchers have found that when information is more relevant to older adults, age differences in source memory are less robust (Hasher, 2003). Further, a recent study found that older adults with better source memory were characterized by healthy cardiovascular markers and psychological traits (higher achievement, less depression, for example) while lower source memory was predicted by relevant life experiences such as being retired and drinking heavily (Cansino & others, 2019). And a recent study indicated that older adults with good retrieval strategies had no deficits in source memory (Salhi & Bergstrom, 2020).

Prospective Memory

Prospective memory involves remembering to do something in the future, such as remembering to take your medicine or remembering to do an errand. Some researchers have found a decline in prospective memory with age (Fine & others, 2021; Rizzo & others, 2020). However, a number of studies show that the cause of the decline is complex and involves factors such as the nature of the task, whether performance on the task is being assessed, and the quality of memory monitoring (Ball, Li, & Bugg, 2020). For example, age-related deficits occur more often in time-based tasks (such as remembering to call someone next Friday) than in event-based tasks (remembering to tell your friend to read a particular

prospective memory Remembering to do something in the future.

Prospective memory involves remembering to do something in the future. The older adult woman here is keeping track of what she plans to buy when she goes to a grocery store the next day.
imtmphoto/shutterstock

book the next time you see her). Recent research also indicates that prospective memory is reduced in individuals with mild cognitive impairment (Lajeunesse & others, 2021) and mild Alzheimer disease (Lecouvey & others, 2019).

Conclusions About Memory and Aging Most, but not all, aspects of memory decline during late adulthood. The decline occurs primarily in explicit, episodic, and working memory (Duarte & Dulas, 2020), not in semantic memory or implicit memory (Davis & others, 2020). A decline in perceptual speed is associated with memory decline (Servant & Evans, 2020). Successful aging does not mean eliminating memory decline altogether, but it does mean reducing or slowing the decline and adapting to it.

Older adults can use certain strategies to reduce memory decline (Hinault & Lemaire, 2020; Jones, Benge, & Scullin, 2021). Researchers have found that strategies involving elaboration and self-referential processing are effective in improving the memory of older adults, actually helping older adults' memory more than younger adults' memory (Trelle, Henson, & Simons, 2015). And in another study, using compensation strategies (for example, managing appointments by routinely writing them on a calendar) was associated with higher levels of independence in everyday function in cognitively normal older adults as well as older adults with mild cognitive impairment (Tomaszewski Farias & others, 2018). Also, a recent study confirmed that when older adults engaged in higher levels of physical activity their memory improved (de Lima & others, 2019).

Review *Connect* Reflect

LG3 Describe what memory is and how it changes through the life span.

Review

- What is memory? What are memory's processes? What is involved in constructing memory? Can new information alter memories?
- How does memory develop in infancy?
- How does memory change in childhood?
- What are some changes in memory during the adult years?

Connect

- How might the changes in the brain during late adulthood be linked to the changes in memory in older adults that were just discussed?

Reflect *Your Own Personal Journey of Life*

- What is your earliest memory? Why do you think this particular situation was so memorable?

4 Thinking

LG4 Characterize thinking and its developmental changes.

What Is Thinking? | Infancy and Childhood | Adolescence | Adulthood

Attention and memory are often steps toward another level of information processing—thinking. What is thinking? How does it change developmentally? What is children's scientific thinking like? Let's explore these questions.

WHAT IS THINKING?

Thinking involves manipulating and transforming information in memory. We think in order to reason, reflect, evaluate ideas, solve problems, and make decisions.

thinking Manipulating and transforming information in memory, in order to reason, reflect, think critically, evaluate ideas and solve problems, and make decisions.

INFANCY AND CHILDHOOD

To explore thinking in infancy and childhood, we ask questions like the following: To what extent do infants form concepts and engage in categorization? What is critical thinking and how can it be encouraged in schools? What is executive function and how does it change developmentally? What is children's scientific thinking like? How do children solve problems?

Concept Formation and Categorization in Infancy

Along with attention, memory, and imitation, concepts are key aspects of infants' cognitive development (Oakes, 2021). **Concepts** are cognitive groupings of similar objects, events, people, or ideas. Without concepts, you would see each object and event as unique, and you would not be able to make any generalizations.

Do infants have concepts? Yes, they do, although we do not know just how early concept formation begins (Quinn, 2015). Using habituation experiments like those described earlier in the chapter, some researchers have found that infants as young as 3 to 4 months of age can group together objects with similar appearances, such as animals (Rakison & Lawson, 2013).

Jean Mandler (2010) argues that these early categorizations are best described as *perceptual categorization*. That is, the categorizations are based on similar perceptual features of objects, such as size, color, and movement, as well as parts of objects, such as legs for animals. Mandler (2004) concludes that it is not until about 7 to 9 months of age that infants form *conceptual* categories rather than just making perceptual discriminations between different categories. In one study of 9- to 11-month-olds, infants classified birds as animals and airplanes as vehicles even though the objects were perceptually similar—airplanes and birds with their wings spread (Mandler & McDonough, 1993) (see Figure 13).

FIGURE **13**

CATEGORIZATION IN 9- TO 11-MONTH-OLDS. These are the type of stimuli used in the study that indicated 9- to 11-month-old infants categorized birds as animals and airplanes as vehicles even though the objects were perceptually similar (Mandler & McDonough, 1993).

In addition to infants categorizing items on the basis of external, perceptual features such as shape, color, and parts, they also may categorize items on the basis of prototypes, or averages, that they extract from the structural regularities of items (Rakison & Lawson, 2013).

Further advances in categorization occur during the second year of life (Rakison & Lawson, 2013). Many infants' "first concepts are broad and global in nature, such as 'animal' or 'indoor thing.' Gradually, over the first two years these broad concepts become more differentiated into concepts such as 'land animal,' then 'dog,' or to 'furniture,' then 'chair'" (Mandler, 2010, p. 1).

Learning to put things into the correct categories—knowing what makes something one kind of thing rather than another kind of thing, such as what makes a bird a bird, or a fish a fish—is an important aspect of learning. As infant development researcher Alison Gopnik (2010, p. 159) pointed out, "If you can sort the world into the right categories—put things in the right boxes—then you've got a big advance on understanding the world."

Do some very young children develop an intense, passionate interest in a specific category of objects or activities? A study of 11-month-old to 6-year-old children confirmed that they do (DeLoache, Simcock, & Macari, 2007). A striking finding was the large gender difference in categories—with an extremely intense interest in particular categories stronger for boys than girls. Categorization of boys' intense interests focused on vehicles, trains, machines, dinosaurs, and balls; girls' intense interests were more likely to involve dress-ups and books/reading (see Figure 14). By the time your author's grandson Alex was 2 years old, he already had developed an intense, passionate interest in the category of vehicles. He categorized vehicles into such subcategories as cars, trucks, earthmoving equipment, and buses. In addition to common classifications of cars into police cars, jeeps, taxis, and such, and trucks into fire trucks, dump trucks, and the like, his categorical knowledge of earthmoving equipment included bulldozers and excavators, and he categorized buses into school buses, London buses, and funky Malta buses (retro buses on the island of Malta). By 2½ years of age, Alex developed an intense, passionate interest in categorizing dinosaurs.

In sum, the infant's advances in processing information—through attention, memory, and concept formation—is much richer, more gradual, and less stage-like, and occurs earlier than was envisioned by earlier theorists, such as Piaget (Bell & Broomell, 2022; Hayne & Herbert, 2021). As leading infant researcher Jean Mandler (2004) concluded, "The human infant shows a remarkable degree of learning power and complexity in what is being learned and in the way it is represented" (p. 304).

Executive Function

Recently, increasing interest has focused on the development of children's **executive function**, an umbrella-like concept that encompasses a number of higher-level cognitive processes linked to the development of the brain's prefrontal cortex. Executive function involves managing one's thoughts to engage in goal-directed behavior and exercise self-control (Bell

Infants are creating concepts and organizing their world into conceptual domains that will form the backbone of their thought throughout life.

concepts Cognitive groupings of similar objects, events, people, or ideas.

executive function An umbrella-like concept that encompasses a number of higher-level cognitive processes linked to the development of the brain's prefrontal cortex. Executive function involves managing one's thoughts to engage in goal-directed behavior and to exercise self-control.

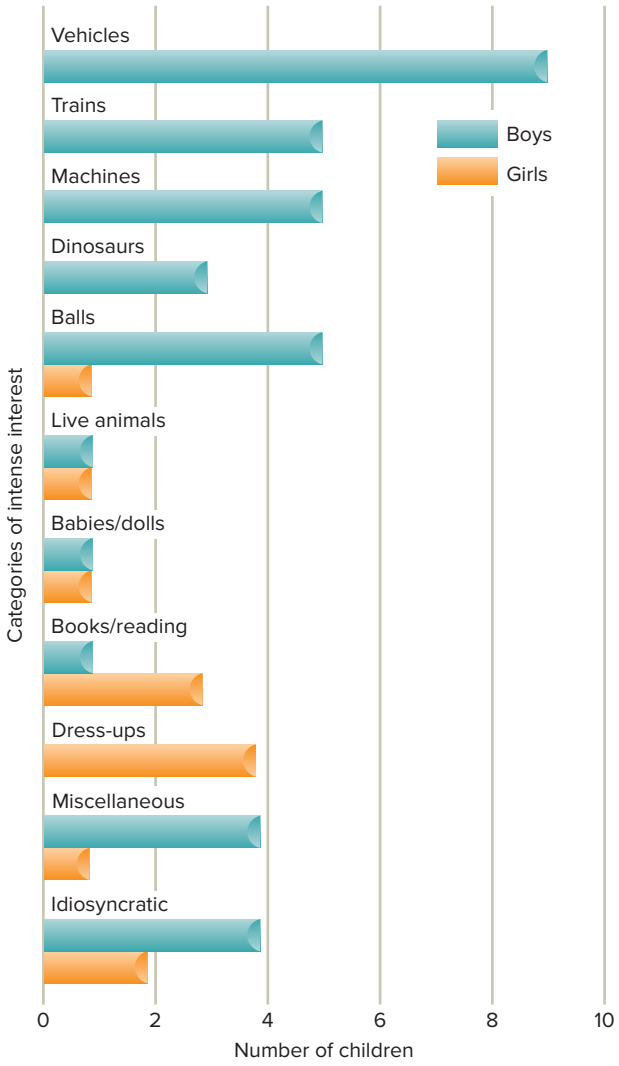

FIGURE **14**

CATEGORIZATION OF BOYS' AND GIRLS' INTENSE INTERESTS.

How did Walter Mischel and his colleagues study young children's delay of gratification? In their research, what later developmental outcomes were linked to the preschoolers' ability to delay gratification?

©Amy Kiley Photography

& Garcia Meza, 2020). Earlier in this chapter, we described the recent interest in *executive attention*, which comes under the umbrella of executive function.

Executive Function in Children In early childhood, executive function especially involves developmental advances in cognitive inhibition (such as inhibiting a strong tendency that is incorrect), cognitive flexibility (such as shifting attention to another item or topic), goal-setting (such as sharing a toy or mastering a skill like catching a ball), and delay of gratification (the ability to forego an immediate pleasure or reward for a more desirable one later) (McClelland, Cameron, & Alonso, 2019). During early childhood, the relatively stimulus-driven toddler is transformed into a child capable of flexible, goal-directed problem solving that characterizes executive function (Zelazo & Muller, 2011).

Walter Mischel and his colleagues (Mischel, 2014; Mischel, Cantor, & Feldman, 1996; Mischel & Moore, 1980; Mischel & others, 2011) have conducted a number of studies of delay of gratification with young children. The main way they assess delay of gratification is to place a young child alone in a room with an alluring marshmallow that is within reach. The children are told that they either can ring a bell at any time and eat the marshmallow or they can wait until the experimenter returns and then get two marshmallows. For the young children who waited for the experimenter to return, what did they do to help them wait? They engaged in a number of strategies to distract their attention from the marshmallow, including singing songs, picking their noses—anything to keep from looking at the marshmallow. Mischel and his colleagues labeled these strategies "cool thoughts" (that is, doing non-marshmallow-related thoughts and activities), whereas they said the young children who looked at the marshmallow were engaging in "hot thoughts." The young children who engaged in cool thoughts were more likely to eat the marshmallow later or to wait until the experimenter returned to the room.

In longitudinal research, Mischel and his colleagues have found that the preschool children who were able to delay gratification became more academically successful, had higher SAT scores and higher grade point averages at the end of college, and coped with stress more successfully as adolescents and emerging adults (Mischel, 2014). And as adults, they made more money in their careers, were more law-abiding, were likely to have a lower body mass index, and were happier than individuals who were unable to delay gratification as preschoolers (Mischel, 2014; Moffitt & others, 2011; Schlam & others, 2013). Although the ability to delay gratification in preschool was linked to academic success and coping in adolescence and competence in adulthood, however, Mischel (2014) emphasizes that adolescents and adults can improve their ability to delay gratification.

Researchers have found that advances in executive function in the preschool years are linked with academic achievement, math skills, attention, language development, and school readiness (Blankenship & others, 2019; Willoughby, Wylie, & Little, 2019). A recent study of preschool children found that a higher level of executive function was linked to learning new words (Kapa & Erikson, 2020). In a study of children in low-income families in the African country of Ghana, executive function assessed at 5 years of age predicted higher subsequent literacy and math skills across the next two years (Wolf & McCoy, 2019). And researchers in another study found that young children who showed delayed development of executive function had a lower level of school readiness (Willoughby & others, 2017). Also, a recent study of preschool children indicated that a lower level of executive function was associated with inattention and hyperactivity (Landis & others, 2021).

Parents and teachers play important roles in the development of executive function (Helm & others, 2020; Ming & others, 2021). One study revealed that sensitive parenting at 3 years of age predicted fewer executive function problems at 4 years of age (Kok & others, 2014). In another study, higher levels of parental education predicted superior executive function in children, whereas harsh parenting forecast lower levels of executive function in children (Halse & others, 2019).

In a recent study of preschool children, conditions of socioeconomic disadvantage exerted a stressful influence on parent-child interactions and in turn on young children's emergent executive function skills (Baker & Brooks-Gunn, 2020). In addition, a recent study revealed that children's executive function was a key factor in linking early-life family income and later academic achievement (Deer, Hastings, & Hostinar, 2020). Further, Ann Masten and her colleagues (Masten, 2013, 2014a, b; Merrick & others, 2019; Monn & others, 2017) have found that executive function and parenting skills are linked to homeless children's success in school. Masten believes that good parenting skills are related to children's executive function. In her words, "When we see kids with good executive function, we often see adults around them that are good self-regulators . . . . Parents model, they support, and they scaffold these skills" (Masten, 2012, p. 11).

How might executive function change in middle and late childhood and be linked to children's success in school? Adele Diamond and Kathleen Lee (2011) highlighted the following dimensions of executive function that they conclude are the most important for 4- to 11-year-old children's cognitive development and school success:

- *Self-control/inhibition.* Children need to develop self-control that will allow them to concentrate and persist on learning tasks, to inhibit their tendencies to repeat incorrect responses, and to resist the impulse to do something now that they would regret later.
- *Working memory.* Children need an effective working memory to efficiently process the masses of information they will encounter as they go through school and beyond. In a recent study that examined different components of executive function, inhibition and working memory were linked to children's mindfulness (Geronimi, Arellano, & Woodruff-Borden, 2020).
- *Flexibility.* Children need to be flexible in their thinking to consider different strategies and perspectives.

Some researchers have found that executive function is a better predictor of school readiness than general IQ (Blair & Razza, 2007). A number of diverse activities have been found to increase children's executive function, such as computerized training that uses games to improve working memory (CogMed, 2013); aerobic exercise (Kvalo & others, 2017); scaffolding of self-regulation (Bodrova & Leong, 2019); mindfulness training (Gallant, 2016); and some types of school curricula (the Montessori curriculum, for example) (Diamond, 2013). In a recent series of meta-analyses to discover which interventions are most likely to increase children's executive function, it was concluded that (a) for typically developing children, mindfulness training was effective; and (b) for non-typically developing children (including those with neurodevelopmental or behavioral problems), strategy teaching involving self-regulation and biofeedback-enhanced relaxation were the most effective (Takacs & Kassai, 2019).

developmental **connection**

Exercise

Recent research indicates that children who are more physically fit have better thinking skills, including those involving executive function, than less physically fit children. Connect to "Health."

Executive Function in Adolescents and Emerging Adults Cognitive development expert Deanna Kuhn (2009) discussed some important characteristics of adolescents' information processing and thinking. In her view, during the later years of childhood and continuing into adolescence, individuals approach cognitive levels that may or may not be achieved, in contrast with the largely universal cognitive levels that young children attain. By adolescence, considerable variation in cognitive functioning is present across individuals. This variability supports the argument that adolescents are producers of their own development to a greater extent than are children. Kuhn (2009) argues that the most important cognitive change in adolescence is improvement in executive control. Especially important is adolescents' and emerging adults' increasing ability to engage in cognitive control, an improvement that continues throughout adolescence and emerging adulthood (Gyurkovics, Stafford, & Levita, 2020).

Two categories of executive function are *cool executive function*, psychological processes involving conscious control driven by logical thinking and critical analysis; and *hot executive function*, psychological processes driven by emotion, with emotion regulation an especially important process (Semenov & Zelazo, 2018). In a recent study of 12- to 17-year-olds, cool executive function increased with age, while hot executive function peaked at 14 to 15 years of age and then declined (Poon, 2018).

A very important aspect of executive function in adolescence is cognitive control. Indeed, for most purposes, executive function and cognitive control can be thought of as synonyms. Cognitive control involves exercising effective control in a number of areas, including focusing attention, reducing interfering thoughts, and being cognitively flexible (Stewart & others, 2017). Cognitive control increases in adolescence and emerging adulthood (Calabro & others, 2020).

How might information processing and thinking skills change in adolescence?
McGraw Hill Education

Think about all the times adolescents need to engage in cognitive control, such as the following situations (Galinsky, 2010):

- Making a real effort to stick with a task, avoiding interfering thoughts or environmental events, and instead doing what is most effective.
- Stopping and thinking before acting to avoid blurting out something that a minute or two later they wished they hadn't said.
- Continuing to work on something that is important but boring when there is something a lot more fun to do, inhibiting their behavior and doing the boring but important task, saying to themselves, "I have to show the self-discipline to finish this."

Another very important aspect of executive function in adolescence is *cognitive flexibility*, which involves being aware of available options and then adapting to one's situation (Uddin, 2021). Before adolescents and emerging adults adapt their behavior in a situation, they must be aware that they need to change their way of thinking and be motivated to do so (Gopnik & others, 2017). Having confidence in their ability to adapt their thinking to a particular situation, an aspect of *self-efficacy,* also is important in being cognitively flexible (Bandura, 2012).

Executive Function and Aging

For the most part, executive function remains strong during early and middle adulthood and plays important roles in many aspects of people's lives. How does executive function change in late adulthood? The prefrontal cortex is one area of the brain that especially shrinks with aging, and recent research has linked this shrinkage with a decrease in working memory and other cognitive activities in older adults (Lloyd & others, 2021).

Executive function skills decline in older adults (Gaillardin & Baudry, 2018). In a recent study of individuals 10 to 86 years of age, executive function increased in adolescence and early adulthood, followed by declines in working memory and inhibition during the thirties and forties, then ongoing declines in executive function during late adulthood (Ferguson, Brundson, & Bradford, 2021). Aspects of working memory that especially decline in older adults involve (1) updating memory representations that are relevant for the task at hand and (2) replacing old information that is no longer relevant (Friedman & others, 2008). Older adults also are less effective at engaging in cognitive control, cognitive flexibility, and cognitive inhibition than when they were younger (Turner & others, 2019).

Although aspects of executive function tend to decline in late adulthood, there is considerable variability in executive function among older adults. A recent study of older adults revealed that the highest-performing group of participants on executive function tasks was differentiated from the lowest-performing group by the following: educational attainment, more novel cognitive activity, lower pulse pressure, younger age, faster gait, lower BMI, and better balance (Caballero & others, 2021). Also, a recent research review of 20 executive function training studies found that overall the training promoted cognitive and neural plasticity in older adults (Nguyen, Murphy, & Andrews, 2019). And a recent study of cognitively healthy older adults indicated that regular physical exercise, especially aerobic exercise, improved key components of executive function—working memory, cognitive flexibility, and inhibitory control (Xiong & others, 2021).

In addition, executive function increasingly is thought to be involved not only in cognitive performance but also in health, emotion regulation, adaptability to life's challenges, motivation, and social functioning (Dixon & others, 2020). For example, in one study, deficits in executive function but not memory predicted a higher risk of coronary heart disease and stroke three years later in older adults (Rostamian & others, 2015). Further, a recent study found that executive function in older adults increased their sense of control over obstacles that interfered with attaining goals, which in turn was associated with higher life satisfaction and positive affect (Toh, Yang, & Hartanto, 2020). And in a recent study, executive function was linked to positive mood in older adults (Cotter & others, 2020).

Critical Thinking

Executive function also involves being able to think critically. Currently, both psychologists and educators are showing considerable interest in critical thinking (Baron, 2020; Sternberg & Halpern, 2020).

Critical thinking involves grasping the deeper meaning of ideas, keeping an open mind about different approaches and perspectives, and deciding for oneself what to believe or do. In this book, the third part of the Review *Connect* Reflect sections challenges you to think critically about a topic or an issue related to the discussion. Thinking critically includes asking not only what happened, but how and why; examining supposed "facts" to determine whether there is evidence to support them; evaluating what other people say rather than immediately

critical thinking Thinking reflectively and productively, and evaluating the evidence.

connecting with careers

Helen Hadani, Ph.D., Developmental Psychologist, Toy Designer, and Associate Director of Research for the Center for Childhood Creativity

Helen Hadani obtained a Ph.D. in developmental psychology from Stanford University. As a graduate student at Stanford, she worked part-time for Hasbro Toys and Apple testing children's software and other computer products for young children. Her first job after graduate school was with Zowie Intertainment, which was subsequently bought by LEGO. In her work as a toy designer there, Helen conducted experiments and focus groups at different stages of a toy's development, and she also studied the age-effectiveness of each toy. In Helen's words, "Even in a toy's most primitive stage of development . . . you see children's creativity in responding to challenges, their satisfaction when a problem is solved or simply their delight in having fun" (Schlegel, 2000, p. 50).

More recently, she began working with the Bay Area Discovery Museum's Center for Childhood Creativity (CCC) in Sausalito, California, an education-focused think tank that pioneers new research, thought-leadership, and teacher training programs that advance creative thinking in all children. Helen is currently the Associate Director of Research for the CCC.

Helen Hadani has worked as both a toy designer and in a museum position that involves thinking of ways to increase children's creative thinking.
Courtesy of Helen Hadani

accepting it as true; and asking questions and speculating beyond what is known to create new ideas and acquire new information.

In the view of experts such as Jacqueline and Martin Brooks (1993, 2001), few schools teach students to think critically. Schools spend much more time getting students to give a single correct answer than encouraging them to come up with new ideas and rethink conclusions. Too often teachers ask students to recite, define, describe, state, and list rather than to analyze, infer, connect, synthesize, criticize, create, evaluate, think, and rethink. As a result, many schools graduate students who think superficially, staying on the surface of problems rather than becoming deeply engaged in meaningful thinking.

According to Ellen Langer (2005), *mindfulness*—being alert, mentally present, and cognitively flexible while going through life's everyday activities and tasks—is an important aspect of thinking critically. Mindful children and adults maintain an active awareness of the circumstances in their lives and are motivated to find the best solutions to challenges they confront (Lux, Decker, & Nease, 2020). Mindful individuals create new ideas, are open to new information, and operate from multiple perspectives. By contrast, mindless individuals are entrapped in old ideas, engage in automatic behavior, and operate from a single perspective.

Recently, Robert Roeser and his colleagues (Roeser & Eccles, 2015; Roeser & Zelazo, 2012; Roeser & others, 2014; Zelazo & others, 2018) have emphasized that mindfulness is an important mental process that children can engage in to improve a number of cognitive and socioemotional skills, such as executive function, focused attention, emotion regulation, and empathy (Roeser & Zelazo, 2012). Some experts have proposed implementing mindfulness training in schools through practices such as using age-appropriate activities that increase children's reflection on moment-to-moment experiences and result in improved self-regulation (Amundsen & others, 2020).

In a recent study, mindfulness training improved self-regulation of attention (Felver & others, 2017). In addition to mindfulness, activities such as yoga, meditation, and tai chi recently have been suggested as candidates for advancing children's cognitive and socioemotional development (Felver & others, 2017). Together these activities are being grouped under the topic of *contemplative science*, a cross-disciplinary term that involves the study of how various types of mental and physical training might enhance children's development (Roeser & Zelazo, 2012; Zelazo & others, 2018). To read about one developmental psychologist who used her training in cognitive development to pursue a career in an applied area, see the *Connecting with Careers* profile.

How do emotions and social contexts influence adolescents' decision making?
Jodi Jacobson/E+/Getty Images

ADOLESCENCE

Earlier, we described some important advances in executive function that take place in adolescence. Here we further discuss two other high-level thinking processes in adolescence—decision making and critical thinking.

Decision Making Adolescence is a time of increased decision making—deciding which friends to choose, which person to date, whether to have sex, buy a car, go to college, and so on (Helm, McCormick, & Reyna, 2018). How competent are adolescents at making decisions? In some reviews, older adolescents are described as more competent than younger adolescents, who in turn are more competent than children (Keating, 2004). Compared with children, young adolescents are more likely to generate different options, examine a situation from a variety of perspectives, anticipate the consequences of decisions, and consider the credibility of sources.

However, the decision-making skills of older adolescents (as well as those of adults) are far from perfect, and having the capacity to make competent decisions does not guarantee that such decisions will be made in everyday life, where breadth of experience often comes into play (Kuhn, 2009). Most people make better decisions when they are calm rather than emotionally aroused, and intense emotional arousal is a common state for adolescents (Duell & Steinberg, 2020). Thus, the same adolescent who makes a wise decision when calm may make an unwise decision when emotionally aroused. In the heat of the moment, then, adolescents' emotions may be more likely to overwhelm their decision-making ability.

The social context plays a key role in adolescent decision making (Defoe & others, 2020). For example, adolescents' decisions to engage in risky behavior are more likely to occur in contexts where alcohol, drugs, and other temptations are readily available. Research reveals that the presence of peers in risk-taking situations increases the likelihood that adolescents will make risky decisions (Albert & Steinberg, 2011a, b). In one study of risk taking involving a simulated driving task, the presence of peers increased adolescents' decision to engage in risky driving by 50 percent but had no effect on adults (Gardner & Steinberg, 2005). One possible explanation is that the presence of peers activates the brain's reward system, especially its dopamine pathways (Steinberg & others, 2018).

To better understand adolescent decision making, Valerie Reyna (2018, 2020) has proposed the **fuzzy-trace theory dual-process model,** which states that decision making is influenced by two cognitive systems—"verbatim" analytical (literal and precise) and gist-based intuitional (simple, bottom-line meaning)—which operate in parallel. In risky situations it is important for an adolescent to quickly get the *gist,* or meaning, of what is happening and glean that the situation is a dangerous context, which can cue personal values that will protect the adolescent from making a risky decision (Reyna, 2018, 2020). Basing judgments and decisions on simple gist is viewed as more beneficial than analytical thinking to adolescents' decision making. In this view, adolescents don't benefit from engaging in reflective, detailed, higher-level cognitive analysis about a decision, especially in high-risk, real-world experiential contexts where they would get bogged down in trivial detail. In such contexts, adolescents need to rely on their awareness that some circumstances are simply so dangerous that they must be avoided at all costs (Brust-Reneck & others, 2017). However, some experts on adolescent cognition argue that in many cases adolescents benefit from both analytical and experiential cognitive systems (Kuhn, 2009).

fuzzy-trace theory dual-process model States that decision making is influenced by two systems—"verbatim" analytical (literal and precise) and gist-based intuition (simple, bottom-line meaning)—which operate in parallel; in this model, gist-based intuition benefits adolescent decision making more than analytical thinking does.

Critical Thinking Among the factors that provide a basis for improvement in critical thinking during adolescence are the following (Keating, 1990):

- Increased speed, automaticity, and capacity of information processing, which free cognitive resources for other purposes;
- Greater breadth of content knowledge in a variety of domains;
- Increased ability to construct new combinations of knowledge;
- A greater range and more spontaneous use of strategies and procedures for obtaining and applying knowledge, such as planning, considering the alternatives, and cognitive monitoring.

ADULTHOOD

Earlier in the chapter, we examined the changes that take place in speed of processing information, attention, memory, and executive function during adulthood. Here we continue to focus on changes in adult cognition, including some gains in thinking in middle adulthood and some of the challenges that older adults face.

Stephen J. Hawking was a world-renowned expert in physics who authored the best-selling book *A Brief History of Time*. Hawking had a neurological disorder that prevented him from walking or talking. He communicated with the aid of a voice-equipped computer. *What distinguishes experts from novices?*
John Phillips/UK Press/Getty Images

Expertise Experience as well as years of learning and effort may bring the rewards of **expertise,** or extensive, highly organized knowledge and understanding of a particular domain (Ericsson & others, 2018). Because it takes so long to attain, expertise shows up more often among middle-aged or older adults than among younger adults (Kim & Hasher, 2005). Individuals may be experts in areas as diverse as physics, art, or knowledge of wine.

Whatever their area of expertise, within that domain experts tend to process information differently from the way novices do (Bransford & others, 2006). Here are some of the characteristics that distinguish experts from novices:

- Experts are more likely to rely on their accumulated experience to solve problems.
- Experts often process information automatically and analyze it more efficiently when solving a problem in their domain than novices do.
- Experts have better strategies and shortcuts for solving problems in their domain than novices do.
- Experts are more creative and flexible in solving problems in their domain than novices are.

Mindfulness Recall that *mindfulness* involves being alert, mentally present, and cognitively flexible while going through life's everyday activities and tasks. A recent study of 53- to 86-year-olds found that engaging in present-moment attention was linked to better affective well-being (Mahio & Windsor, 2021). Recently, there has been growing interest in training older adults to use techniques that promote mindfulness, particularly meditation (Reangsing, Rittiwong, & Kraenzle Schneider, 2021). Some, but not all, studies have shown that mindfulness training improves older adults' cognitive functioning (Kovach & others, 2018). In one study, a mindfulness-based stress reduction program involving meditation improved older adults' memory and inhibitory control (Lenze & others, 2014). Further, recent research found that a mindfulness-awareness program improved the working memory and divided attention of older adults with mild cognitive impairment (Yu & others, 2021). And in a recent study of middle-aged and older adults, greater mindfulness was associated with more positive aging expectations (Fiocco & Meisner, 2020).

Education, Work, and Health Education, work, and health are three important influences on the cognitive functioning of older adults . They are also three of the most important factors involved in understanding why cohort effects should be taken into account in studying the cognitive functioning of older adults. Indeed, cohort effects are highly relevant in the study of cognitive aging (Schaie, 2013, 2016). For example, one study found that older adults assessed in 2013–2014 engaged in a higher level of abstract reasoning than their counterparts who were assessed two decades earlier (Gerstorf & others, 2015). And a recent study of older adults in 10 European countries revealed improvements in memory between 2004 and 2013, with the changes being especially positive for cohorts of older adults who had decreased rates of cardiovascular disease and increased levels of exercise and educational achievement (Hessel & others, 2018).

Education Successive generations in America's twentieth century were better educated, and this trend continues in the twenty-first century (Schaie, 2013, 2016). Educational experiences are positively correlated with scores on intelligence tests and information-processing tasks, such as memory exercises (Peeters, Kenny, & Lawlor, 2020). One study found that older adults with a higher level of education had better cognitive functioning than those with less education (Rapp & others, 2013). Also, a recent study of older Mexican adults revealed that in addition to one's own education, a spouse's education was associated with better cognitive ability (Saenz, Beam, & Zelinski, 2020). Further, a recent study indicated that a higher level of education has a strong effect on older adults' working memory in the United States (Saito & others, 2020).

developmental **connection**
Education
A criticism of the No Child Left Behind legislation is that it does not give adequate attention to the development of critical thinking skills. Connect to "Schools, Achievement, and Work."

developmental **connection**
Work
Cognitive ability is one of the best predictors of job performance in older adults. Connect to "Schools, Achievement, and Work."

Work Successive generations have also had work experiences that include a stronger emphasis on cognitively oriented labor. Our great-grandparents and grandparents were more likely to be manual laborers than were our parents, who are more likely to be involved in cognitively oriented occupations. As the industrial society continues to be replaced by the information society, younger generations will have more experience in jobs that require considerable cognitive investment. The increased emphasis on complex information processing in jobs likely enhances an individual's intellectual abilities (Lovden, Backman, & Lindenberger, 2017). For example, in a recent Australian study, older adults who had retired from occupations that involved higher complexity maintained their cognitive advantage over their counterparts whose occupations had involved lower complexity (Lane & others, 2017). And, in a recent study of Puerto Rican older adults, a higher complexity of work was associated with a reduced risk of cognitive impairment (Andel & others, 2019).

Health Successive generations have also been healthier in late adulthood as better treatments for a variety of illnesses (such as hypertension) have been developed. Many of these illnesses, such as stroke, heart disease, and diabetes, have a negative impact on intellectual performance (Gunning & Jaywant, 2020). For example, a recent study of older Latinxs revealed that cardiovascular risk factors were linked to lower cognitive functioning (Tarraf & others, 2020). In addition, a recent study revealed that high blood pressure was associated with lower cognitive function in older adults (Naharci & Katipoglu, 2021). Researchers also have found age-related cognitive decline in adults with mood disorders such as depression (Wei & others, 2019). For example, a recent study of older adults indicated that depression was linked to lower executive attention, memory, and language performance (MacAulay & others, 2020). Thus, some of the decline in intellectual performance found in older adults is likely due to health-related factors rather than to age per se (Gunning & Jaywant, 2020).

A number of research studies have found that exercise is linked to improved cognitive functioning in older adults (Erlenbach, McAuley, & Gothe, 2021). Walking or any other aerobic exercise appears to get blood and oxygen pumping to the brain, which can help people think more clearly (Redwine & others, 2020). A recent study found that the risk of cognitive decline was lower among older adults who engaged in either moderate-to-high-intensity exercise or low-intensity exercise (Endeshaw & Goldstein, 2021). Dietary patterns also are linked to cognitive functioning in older adults (Chen & others, 2021). For example, a recent research review concluded that multinutrient approaches using the Mediterranean diet are linked to a lower risk of cognitive impairment (Abbatecola, Russo, & Barbieri, 2018).

A final aspect of health that is related to cognitive functioning in older adults is *terminal decline*. This concept emphasizes that changes in cognitive functioning may be linked more to distance from death or cognition-related pathology than to distance from birth (Wilson & others, 2018). In a recent study of more than 1,000 older adults (mean age = 79) who were followed for 10+ years, overall cognitive decline accelerated considerably at 3.7 years on

average before death (Wilson & others, 2020). In terms of specific cognitive factors, terminal decline accounted for 70 percent of episodic memory loss, 65 percent of semantic memory loss, 57 percent of working memory loss, 53 percent of visuospatial loss, and 52 percent of perceptual speed loss.

Cognitive Neuroscience and Aging Certain regions of the brain are involved in links between aging, brain health, and cognitive functioning (Argiris, Stern, & Habeck, 2021). In this section, we further explore the substantial increase in interest in the brain's role in aging and cognitive functioning. The field of *developmental cognitive neuroscience* has emerged as the major discipline that studies links between development, the brain, and cognitive functioning (Stuss & Craik, 2021). This field especially relies on brain-imaging techniques, such as functional magnetic resonance imaging (fMRI), positron-emission tomography (PET), and DTI (diffusion tensor imaging), to reveal the areas of the brain that are activated when individuals are engaging in certain cognitive activities (Cohen, Porges, & Gullett, 2021). For example, as an older adult is asked to encode and then retrieve verbal materials or images of scenes, the older adult's brain activity will be monitored by an fMRI brain scan.

Changes in the brain can influence cognitive functioning, and changes in cognitive functioning can influence the brain. For example, aging of the brain's prefrontal cortex may produce a decline in working memory. And when older adults do not regularly use their working memory, neural connections in the prefrontal lobe may atrophy. Further, cognitive interventions that activate older adults' working memory may increase these neural connections.

Although it is in its infancy as a field, the cognitive neuroscience of aging is beginning to uncover some important links between aging, the brain, and cognitive functioning (Heilman & Nadeau, 2021). These include the following:

- Neural circuits in specific regions of the brain's prefrontal cortex decline, and this decline is linked to poorer performance by older adults on complex reasoning tasks, working memory, and episodic memory tasks (Larabee, 2020) (see Figure 15).
- Older adults are more likely than younger adults to use both hemispheres of the brain to compensate for age-related declines in attention, memory, and language (Esteves & others, 2021). Two neuroimaging studies revealed that better memory performance in older adults was linked to higher levels of activity in both hemispheres of the brain in processing information (Angel & others, 2011; Manenti, Cotelli, & Miniussi, 2011).
- Functioning of the hippocampus declines but to a lesser degree than the functioning of the frontal lobes in older adults (Antonenko & Floel, 2014). In K. Warner Schaie's (2013) research, individuals whose memory and executive function declined in middle age had more hippocampal atrophy in late adulthood, while those whose memory and executive function improved in middle age did not show a decline in hippocampal functioning in late adulthood.
- Patterns of neural decline with aging are more evident for retrieval than encoding (Gutchess & others, 2005).
- Compared with younger adults, older adults often show greater activity in the frontal and parietal lobes of the brain on simple tasks, but as attentional demands increase, older adults display less effective functioning in the frontal and parietal lobes of the brain that involve cognitive control (Campbell & others, 2012).
- Cortical thickness in the frontoparietal network predicts executive function in older adults (Stuss & Craik, 2021).
- Younger adults have better connectivity between brain regions than older adults do (Edde & others, 2021).
- An increasing number of cognitive and fitness training studies include brain-imaging techniques such as fMRI to assess the results of such training on brain functioning (Peven, Stillman, & Erickson, 2020). In one study, older adults who walked one hour a day three days a week for six months showed increased volume in the frontal and temporal lobes of the brain (Colcombe & others, 2006).

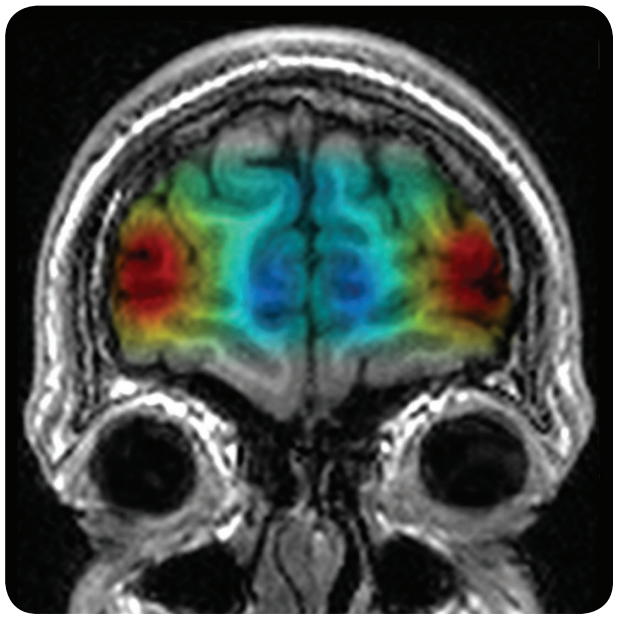

FIGURE **15**

THE PREFRONTAL CORTEX. Advances in neuroimaging are allowing researchers to make significant progress in connecting changes in the brain with cognitive development. Shown here is an fMRI of the brain's prefrontal cortex. *What links have been found between the prefrontal cortex, aging, and cognitive development?*

The mind is an enchanting thing.

—Marianne Moore
American Poet, 20th Century

Denise Park and Patricia Reuter-Lorenz (2009; Reuter-Lorenz & Park, 2014) proposed a neurocognitive scaffolding view of connections between the aging brain and cognition. In this view, increased activation in the prefrontal cortex with aging reflects an adaptive brain that is compensating for the challenges of declining neural structures and function, as well as declines in various aspects of cognition, including working memory and long-term memory. Scaffolding involves the use of complementary neural circuits to protect cognitive functioning in an aging brain. Among the factors that can strengthen brain scaffolding are cognitive engagement and exercise (Hegberg, Dev, & Hayes, 2020; Wu & Rebok, 2020).

Use It or Lose It Changes in cognitive activity patterns might result in disuse and consequent atrophy of cognitive skills (Glover & others, 2021). This concept is captured in the expression "use it or lose it." Mental activities that are likely to benefit the maintenance of cognitive skills in older adults include reading books, doing crossword puzzles, and attending lectures and concerts. "Use it or lose it" also is a significant component of the engagement model of cognitive optimization that emphasizes how intellectual and social engagement can buffer age-related declines in intellectual development (Reuter-Lorenz & Park, 2014). The following studies support the "use it or lose it" concept and the engagement model of cognitive optimization:

- In two different samples of older adults, a higher level of cognitive activity (reading newspapers, magazines, and books; writing letters; and playing games) was linked to better cognitive functioning (executive function, processing speed, and semantic processing) (Casaletto & others, 2020).
- In the Mayo Clinic Study of Aging (Krell-Roesch & others, 2019), engaging in a higher number of mentally stimulating activities (reading, computer use, social activities, playing games, and craft activities) was associated with a decreased risk of mild cognitive impairment.
- A recent research review concluded that low levels of social isolation characterized by high engagement in social activities and large social networks were linked to better cognition (memory and executive function, for example) in older adults (Evans & others, 2019).
- In the Baltimore Experience Corps program, an activities engagement–health promotion for older adults that involved their volunteerism in underserved urban elementary schools–improved older adults' cognitive and brain functioning (Parisi & others, 2015).
- In recent research with older adults in China, high levels of both cognitive activity and physical activity were associated with maintaining and preserving cognitive functioning (Wu & others, 2021).

To read further about "use it or lose it," see *Connecting Development to Life.*

Cognitive Training If older adults are losing cognitive skills, can these skills be regained through training? An increasing number of research studies indicate that they can be restored to some extent (Wu & Rebok, 2020).

Consider a study of 60- to 90-year-olds which found that sustained engagement in cognitively demanding, novel activities improved the older adults' episodic memory (Park & others, 2014). To produce this result, the older adults spent an average of 16.5 hours a week for three months learning to quilt or how to use digital photography. Consider also a study of 60- to 90-year-olds in which iPad training 15 hours a week for 3 months improved their episodic memory and processing speed more than engaging in social or non-challenging activities (Chan & others, 2016).

Meta-examinations of four longitudinal observational studies (Long Beach Longitudinal Study; Origins of Variance in the Oldest-old [Octo-Twin] Study in Sweden; Seattle Longitudinal Study; and Victoria Longitudinal Study in Canada) of older adults' naturalistic cognitive activities found that changes in cognitive activity predicted cognitive outcomes as long as two decades later (Brown & others, 2012; Lindwall & others, 2012; Mitchell & others, 2012; Rebok & others, 2014). However, the hypothesis that engaging in cognitive activity at an earlier point in development would improve older adults' ability to later withstand cognitive decline was not supported. On a positive note, when older adults continued to increase their engagement in cognitive and physical activities, they were better able to maintain their cognitive functioning in late adulthood.

The Stanford Center for Longevity (2011) and together the Stanford Center for Longevity and the Max Planck Institute for Human Development (2014) reported information based on

connecting development to life

The Remarkable Helen Small

In 2010, 90-year-old Helen Small completed her master's degree at the University of Texas at Dallas (UT-Dallas). The topic of her master's degree research project was romantic relationships in late adulthood. Helen said that she only interviewed one individual who was older than she was—a 92-year-old man.

I (your author, John Santrock) first met Helen when she took my undergraduate course in life-span development in 2006. After the first test, Helen stopped showing up and I wondered what had happened to her. It turns out that she had broken her shoulder when she tripped over a curb while hurrying to class. The next semester, she took my class again and did a great job in it, even though the first several months she had to take notes with her left hand (she's right-handed) because of her lingering shoulder problem.

Helen Small with the author of your text, John Santrock, in his undergraduate course on life-span development at the University of Texas at Dallas in spring 2012. Working around her busy schedule, Helen would return each semester to talk with students in the class about cognitive aging.
Dr. John Santrock

WHY NOT?
My seventy year plan for a college degree
Helen Small
Why Not? is a rare book that teaches people how to positively overcome speedbumps in the road of life.
TONY JEARY
Speaker and Best Selling Author

Helen Small published her first book, *Why Not? My Seventy Year Plan for a College Degree*, in 2011 at the age of 91.
Courtesy of Helen Small

Helen grew up in the Great Depression and first went to college in 1938 at the University of Akron, where she only attended for one year. She got married and her marriage lasted 62 years. After her husband's death, Helen went back to college. When I interviewed her several years ago, she told me that she had promised her mother that she would finish college. Her most important advice for college students: "Finish college and be persistent. When you make a commitment, always see it through. Don't quit. Go after what you want in life."

Helen not only was a cognitively fit older adult, she also was physically fit. She regularly worked out—aerobically on a treadmill for about 30 minutes and then on six different weight machines.

What struck me most about Helen when she took my undergraduate course in life-span development was how appreciative she was of the opportunity to learn and how tenaciously she pursued studying and doing well in the course. Helen was quite popular with the younger students in the course, and she was a terrific role model for them.

After her graduation, I asked her what she planned to do during the next few years and she responded, "I've got to figure out what I'm going to do with the rest of my life." Helen came back each semester to my course in life-span development when we were discussing cognitive aging. She wowed the class and was an inspiration to all who came in contact with her.

What did Helen do to stay cognitively fit? She worked as a public ambassador both for Dr. Denise Park's Center for Vital Longevity at UT-Dallas and the Perot Science Museum. And Helen was active in delivering meals through the Meals on Wheels organization that seeks to reduce hunger and social isolation in older adults. She also wrote her first book: *Why Not? My Seventy Year Plan for a College Degree* (Small, 2011). It's a wonderful, motivating invitation to live your life fully and reach your potential no matter what your age. Following an amazing, fulfilling life, Helen Small passed away in 2017 at the age of 97.

a consensus of leading scientists in the field of aging on the extent to which the cognitive skills of older adults can be improved. One of their concerns is the misinformation given to the public touting products that supposedly improve the functioning of the mind but for which there is no scientific evidence (Willis & Belleville, 2016). Nutritional supplements and software products have been advertised as "magic bullets" to slow the decline of mental functioning and improve the mental ability of older adults. Some of the claims are reasonable but not scientifically tested, and others are unrealistic and implausible. A research review of dietary supplements and cognitive aging linked ginkgo biloba to improvements in some aspects of attention in older adults and omega-3 polyunsaturated fatty acids to a reduced risk of age-related

To what extent can training improve the cognitive functioning of older adults?
Stewart Cohen/Pam Ostrow/Blend Images/Alamy Stock Photo

cognitive decline (Gorby, Brownell, & Falk, 2010). In this research review, there was no evidence of cognitive improvements in aging adults who consumed ginseng and glucose. However, an experimental study with 50- to 75-year-old females found that those who took fish oil for 26 weeks had improved executive function and beneficial effects in a number of areas of brain functioning compared with their female counterparts who took a placebo pill (Witte & others, 2014). In other studies, fish oil supplementation was linked to higher cognitive scores and less atrophy in one or more brain regions (Daiello & others, 2015) and improvements in the working memory of older adults (Boespflug & others, 2016). Overall, though, research has not provided consistent plausible evidence that most dietary supplements can facilitate major cognitive improvements in aging adults over a number of years.

Some software-based cognitive training games have been found to improve older adults' cognitive functioning, but the gains typically occur only for the specific cognitive task assessed and do not generalize to broad effects on cognitive performance (Rogers, Blocker, & Dupuy, 2020). For example, a study of 60- to 85-year-olds found that playing a multitasking video game that simulates day-to-day driving experiences (NeuroRacer) improved cognitive control skills, such as sustained attention and working memory, after training on the video game and six months later (Anguera & others, 2013). Further, in a recent meta-analysis it was concluded that video games have small training effects on improving older adults' memory but no positive outcomes for other cognitive functions (Mansor, Chow, & Halaki, 2020). Also, recall our discussion earlier in the chapter that indicated regular exercise can improve the cognitive functioning of older adults. A number of research studies have found that exercise is linked to improved cognitive functioning in older adults (Peven, Stillman, & Erickson, 2020). Walking or any other aerobic exercise appears to get blood and oxygen pumping to the brain, which can help people think more clearly. For example, a recent study confirmed that when older adults engaged in higher levels of physical activity their memory improved (de Lima & others, 2019). And a recent study of older adults indicated that an in-home exergame training program improved their executive function (Adcock & others, 2020).

In sum, some improvements in the cognitive vitality of older adults can be accomplished through cognitive and fitness training (Hinault & Lemaire, 2020; Wu & others, 2021). However, the resulting cognitive improvements often occur only when there is a substantial amount of effortful practice over a long period of time (Hambrick, 2014). And benefits have not been observed in all studies (Salthouse, 2019). Further research is needed to determine more precisely which cognitive improvements occur in older adults as a result of training (Anderson & Winocur, 2020; Malmberg Gavelin & others, 2021).

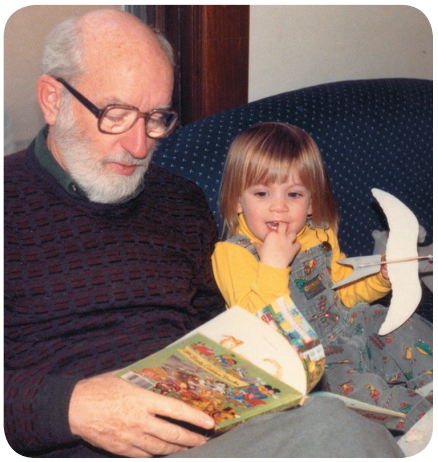
5 Metacognition

LG5 Define metacognition and summarize its developmental changes.

What Is Metacognition? | Theory of Mind | Metacognition in Adolescence and Adulthood

As mentioned at the beginning of this chapter, metacognition is "thinking about thinking or knowing about knowing." John Flavell (1971, 1976) pioneered theory and research on metacognition, which has developed into a major research field in the study of cognitive development. In this section, we examine the role of metacognition in performing cognitive tasks, theory of mind, children's memory abilities, and metacognition in adolescents and adults.



Cognitive developmentalist John Flavell is a pioneer in providing insights about children's thinking. Among his many contributions are establishing the field of metacognition and conducting numerous studies in this area, including metamemory and theory of mind studies.
Courtesy of Dr. John Flavell

WHAT IS METACOGNITION?

Metacognition can take many forms. It includes thinking about and knowing when and where to use particular strategies for learning or for solving problems (Pennequin & others, 2020; Wang & others, 2021). Conceptualization of metacognition includes several dimensions of executive function, such as planning (deciding how much time to spend focusing on a task, for example), evaluation (monitoring progress toward task completion, for example), and self-regulation (modifying strategies as the task progresses, for example) (Bellon, Fias, & Smedt, 2020).

Metacognition helps people to perform many cognitive tasks more effectively (Doherty & others, 2021; Zakrzewski, Sanders, & Berry, 2021). A study of young children found that their metacognitive ability in the numerical domain predicted their school-based math knowledge (Vo & others, 2014). Also, in a recent study of 7- and 8-year-olds, task-specific metacognitive monitoring skills in noticing one's own errors and learning from mistakes were linked to superior performance in arithmetic (Bellon, Fias, & De Smedt, 2019). Another study found that metacognition played an important role in adolescents' ability to generate effective hypotheses about solving problems (Kim & Pedersen, 2010).

Metamemory, individuals' knowledge about memory, is an especially important form of metacognition. Metamemory includes general knowledge about memory, such as knowing that recognition tests (for example, multiple-choice questions) are easier than recall tests (for example, essay questions). It also encompasses knowledge about one's own memory, such as knowing whether you have studied enough for an upcoming test.

By 5 or 6 years of age, children usually know that familiar items are easier to learn than unfamiliar ones, that short lists are easier to remember than long ones, that recognition is easier than recall, and that forgetting becomes more likely over time (Lyon & Flavell, 1993). However, in other ways young children's metamemory is limited. They don't understand that related items are easier to remember than unrelated ones or that remembering the gist of a story is easier than remembering information verbatim (Kreutzer, Leonard, & Flavell, 1975). By fifth grade, students understand that gist recall is easier than verbatim recall.

Preschool children also have an inflated opinion of their memory abilities. For example, in one study, a majority of preschool children predicted that they would be able to recall all ten items on a list of ten items. When tested, none of the young children managed this feat (Flavell, Friedrichs, & Hoyt, 1970). As they move through the elementary school years, children give more realistic evaluations of their memory skills (Schneider, 2011).

Preschool children also have little appreciation for the importance of cues for memory, such as "It helps when you can think of an example of it." By 7 or 8 years of age, children better appreciate the importance of cueing for memory.

In general, children's understanding of their memory abilities and their skill in evaluating their performance on memory tasks are relatively poor at the beginning of the elementary school years but improve considerably by 11 to 12 years of age (Bjorklund & Rosenbaum, 2000).

THEORY OF MIND

Even young children are curious about the nature of the human mind (Gerson & Meyer, 2021; Grosse Wiesmann & others, 2020). They have a **theory of mind,** which refers to awareness of one's own mental processes and the mental processes of others (Peterson & Wellman, 2019).

metamemory Knowledge about memory.

theory of mind Thoughts about how one's own mental processes work and the mental processes of others.

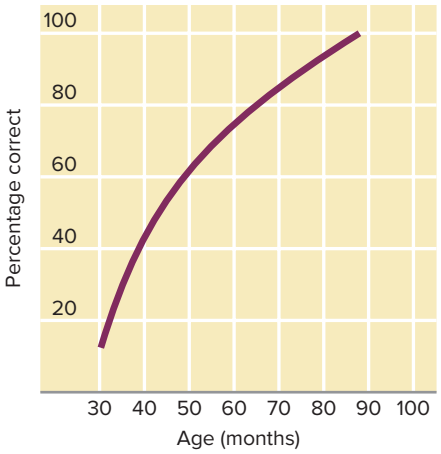


FIGURE 16

DEVELOPMENTAL CHANGES IN FALSE-BELIEF PERFORMANCE. False-belief performance—the child's understanding that a person has a false belief that contradicts reality—dramatically increases from 2½ years of age through the middle of the elementary school years. In a summary of the results of many studies, 2½-year-olds gave incorrect responses about 80 percent of the time (Wellman, Cross, & Watson, 2001). At 3 years 8 months, they were correct about 50 percent of the time and, after that, they gave increasingly correct responses.

Studies of theory of mind view the child as "a thinker who is trying to explain, predict, and understand people's thoughts, feelings, and utterances" (Harris, 2006, p. 847).

Developmental Changes in Children Although whether infants have a theory of mind continues to be questioned by some (Rakoczy, 2012), the consensus is that some changes occur quite early in development, as we see next (Poulin-Dubois, 2020). From 18 months to 3 years of age, children begin to understand three mental states:

- *Perceptions*. By 2 years of age, children recognize that another person will see what's in front of her own eyes instead of what's in front of the child's eyes (Lempers, Flavell, & Flavell, 1977), and by 3 years of age, they realize that looking leads to knowing what's inside a container (Pratt & Bryant, 1990).
- *Emotions*. The child can distinguish between positive (for example, happy) and negative (for example, sad) emotions. A child might say, "Tommy feels bad."
- *Desires*. All humans have some sort of desires. But when do children begin to recognize that someone else's desires may differ from their own? Toddlers recognize that if people want something, they will try to get it. For instance, a child might say, "I want my mommy."

At age 2 to 3, children understand the way that desires are related to actions and to simple emotions. For example, they understand that people will search for what they want and that if they obtain it, they are likely to feel happy, but if they don't get it they will keep searching for it and are likely to feel sad or angry (Wellman & Woolley, 1990). Children also refer to desires earlier and more frequently than they refer to cognitive states such as thinking and knowing (Bartsch & Wellman, 1995).

One of the landmark developments in understanding others' desires is recognizing that someone else may have desires that differ from one's own (Wellman, 2011, 2015). Eighteen-month-olds understand that their own food preferences may not match the preferences of others—they will give an adult the food to which she says "Yummy!" even if the food is something that the infants detest (Repacholi & Gopnik, 1997). As they get older, they can verbalize that they themselves do not like something but an adult might like it (Flavell & others, 1992).

Between the ages of 3 and 5, children come to understand that the mind can represent objects and events accurately or inaccurately (Tompkins & others, 2017). The realization that people can have *false beliefs*—beliefs that are not true—develops in a majority of children by the time they are 5 years old (Wellman, Cross, & Watson, 2001) (see Figure 16).

This point is often described as a pivotal one in understanding the mind—recognizing that beliefs are not just mapped directly into the mind from the surrounding world, but also that different people can have different, and sometimes incorrect, beliefs (Grosso & others, 2019). In a classic false-belief task, young children were shown a Band-Aids box and asked what was inside it (Jenkins & Astington, 1996). To the children's surprise, the box actually contained pencils. When asked what a child who had never seen the box would think was inside it, 3-year-olds typically responded, "Pencils." However, the 4- and 5-year-olds, grinning at the anticipation of the false beliefs of other children who had not seen what was inside the box, were more likely to say "Band-Aids."

In a similar task, children are told a story about Sally and Anne: Sally places a toy in a basket and then leaves the room (see Figure 17). In her absence, Anne takes the toy from the basket and places it in a box. Children are

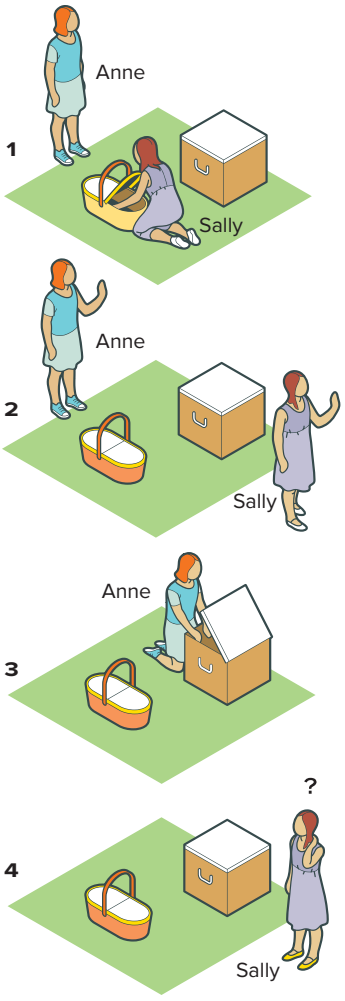

FIGURE 17

THE SALLY AND ANNE FALSE-BELIEF TASK. In the false-belief task, the skit above in which Sally has a basket and Anne has a box is shown to children. Sally places a toy in her basket and then leaves. While Sally is gone and can't watch, Anne removes the toy from Sally's basket and places it in her box. Sally then comes back and the children are asked where they think Sally will look for her toy. Children are said to "pass" the false-belief task if they understand that Sally looks in her basket first before realizing the toy isn't there.

asked where Sally will look for the toy when she returns. The major finding is that 3-year-olds tend to fail false-belief tasks, saying that Sally will look in the box (even though Sally could not know that the toy had been moved to this new location). Four-year-olds and older children tend to pass the task, correctly saying that Sally will have a "false belief"—she will think the object is in the basket, even though that belief is now false. The conclusion from these studies is that children younger than 4 years old do not understand that it is possible to have a false belief.

One example of a limitation in 3- to 5-year-olds' understanding the mind is how they think about thinking. Preschoolers often underestimate when mental activity is likely to take place. For example, they sometimes think that a person who is sitting quietly or reading is not actually thinking very much (Flavell, Green, & Flavell, 1995). Their understanding of their own thinking is also limited. One study revealed that even 5-year-olds have difficulty reporting their thoughts (Flavell, Green, & Flavell, 1995). Children were asked to think quietly about the room in their home where they kept their toothbrushes. Shortly after this direction, many children denied they had been thinking at all and failed to mention either a toothbrush or a bathroom. In another study, when 5-year-olds were asked to try to have no thoughts at all for about 20 seconds, they reported that they were successful at doing this (Flavell, Green, & Flavell, 2000). By contrast, most of the 8-year-olds said they had engaged in mental activity during the 20 seconds and reported specific thoughts.

It is only beyond the preschool years—at approximately 5 to 7 years of age—that children have a deepening appreciation of the mind itself rather than just an understanding of mental states. For example, they begin to recognize that people's behaviors do not necessarily reflect their thoughts and feelings (Flavell, Green, & Flavell, 1993). Not until middle and late childhood do children see the mind as an active constructor of knowledge or a processing center (Flavell, Green, & Flavell, 1998) and move from understanding that beliefs can be false to realizing that the same event can be open to multiple interpretations (Carpendale & Chandler, 1996). For example, in one study, children saw an ambiguous line drawing (for example, a drawing that could be seen as either a duck or a rabbit); one puppet told the child she believed the drawing was a duck while another puppet told the child he believed the drawing was a rabbit (see Figure 18). Before the age of 7, children said that there was one right answer and that it was not okay for the two puppets to have different opinions.

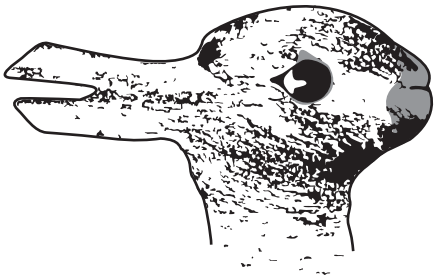

FIGURE **18**
AMBIGUOUS LINE DRAWING.

Individual Differences As in other developmental research, there are individual differences in the ages when children reach certain milestones in their theory of mind. *Executive function,* which involves goal-directed behavior and self-control (as discussed earlier in the chapter), is linked to the development of a theory of mind (Zelazo & others, 2018). For example, in one executive function task, children are asked to say the word *night* when they see a picture of a sun, and the word *day* when they see a picture of a moon and stars. Children who perform better at executive function tasks seem also to have a better understanding of theory of mind (Benson & Sabbagh, 2017). Language development also likely plays a prominent role in the increasingly reflective nature of theory of mind as children go through the early childhood and middle and late childhood years (Ebert, 2020).

Among other factors that influence children's theory of mind development are advances in prefrontal cortex functioning (Powers, Chavez, & Heatherton, 2016), engagement in pretend play (Lillard & Kavanaugh, 2014), and various aspects of social interaction (Spaulding, 2020). Among the social interaction factors that advance children's theory of mind are being securely attached to parents who engage children in mental state talk ("That's a good thought you have" or "Can you tell what he's thinking?") (Devine & Hughes, 2018), having older siblings and friends who engage in mental state talk (Devine & Hughes, 2018), and living in a higher-socioeconomic-status family (Devine & Hughes, 2019). A recent study found that parental engagement in mind-mindedness (viewing children as mental agents by making mind-related comments to them) advanced preschool children's theory of mind (Hughes, Devine, & Wang, 2018). Also, research indicates that children who have an advanced theory of mind are more popular with their peers and have better social skills in peer relations (Peterson & others, 2016).

Another individual difference in understanding the mind involves autism (Andres-Roqueta & Katsos, 2020). Autism can usually be diagnosed by the age of 3 years and sometimes earlier. Children with autism show a number of behaviors different from other children their age, including deficits in theory of mind, social interaction, and communication (Garon, Smith, &

A young boy with autism. *What are some characteristics of autistic children? What are some deficits in autistic children's theory of mind?*
Rob Crandall/Alamy Stock Photo

Bryson, 2018). A recent study found that theory of mind predicted the severity of autism in children (Hoogenhout & Malcolm-Smith, 2017).

Developmental Changes in Theory of Mind in Adolescence and Adulthood Most research on theory of mind has focused on children. Recently, though, there have been efforts to chart developmental changes in theory of mind in adolescence and adulthood.

Adolescence The social worlds of adolescents become more complex than in childhood, and the importance of interpersonal relationships in adolescence motivates adolescents to understand not only their own but others' minds as well (Gabriel & others, 2021; Meinhardt-Injac, Daum, & Meinhardt, 2020). Adolescents also are more likely than children to engage in *recursive thinking*, a term used to describe thinking about what other people are thinking about. With advancing cognitive skills, such as executive function, adolescents are better at understanding and predicting others' behavior than children are (Kilford, Garrett, & Blakemore, 2016). And adolescents are better than children at interpreting others' feelings and motives even when others' feelings and motives are not directly observable, although adolescents still make numerous errors in such efforts (Blakemore, 2018).

Adulthood For most of adulthood, individuals retain the theory of mind accomplishments they developed in childhood and adolescence, such as those involving belief, desire, knowledge, intention, and perspective taking. An important aspect of adult life is how people employ these concepts to cope with the challenges of their social world, such as detecting when someone is lying or keeping up with a fast-moving conversation. But adults don't always use their theory of mind skills in everyday life. In one study, adults did not use their theory of mind skills to discredit a speaker who clearly lacked key facts about a topic (Keysar, Lin, & Barr, 2003). Further, too often adults neglect to take into account others' perspectives (Epley & others, 2004).

Research also indicates that theory of mind abilities decline in older adults (Hughes & others, 2019). This decline is likely related to declines in other cognitive skills, such as executive function, and changes in the brain's prefrontal cortex in older adults (Calso, Besnard, & Allain, 2020).

METACOGNITION IN ADOLESCENCE AND ADULTHOOD

Metacognition is increasingly recognized as a very important cognitive skill not only in adolescence but also in emerging adulthood.

Adolescence Compared with children, adolescents have an increased capacity to monitor and manage cognitive resources to effectively meet the demands of a learning task (Kuhn, 2009). This increased metacognitive ability results in improved cognitive functioning and learning (Nussenbaum & others, 2020). A longitudinal study revealed that from 12 to 14 years of age, young adolescents increasingly used metacognitive skills and used them more effectively in math and history classes than in other subjects (van der Stel & Veenman, 2010). For example, 14-year-olds monitored their own text comprehension more frequently and did so more effectively than their younger counterparts. Another study documented the central roles of metacognitive skills, such as planning, strategizing, and monitoring, in college students' ability to think critically (Magno, 2010).

How might metacognition change as people get older?
Rawpixel/123RF

An important aspect of cognitive functioning and learning is determining how much attention will be allocated to an available resource. Evidence is accumulating that adolescents have a better understanding of how to effectively deploy their attention to different aspects of a task than children do (Kuhn, 2009). Further, adolescents have a better meta-level understanding of strategies–that is, they are better able to figure out the best strategy to use and when to use it in performing a learning task.

Keep in mind, though, that there is considerable individual variation in adolescents' metacognition (Dos Santos Kawata & others, 2021). Indeed, some experts argue that individual variation in metacognition becomes much more pronounced in adolescence than in childhood (Kuhn & Franklin, 2006). Thus, some adolescents are quite good at using metacognition to improve their learning, while others are far less effective.

Adulthood and Aging By middle age, adults have accumulated a great deal of metacognitive knowledge. They can draw on this metacognitive knowledge to help them combat a decline in memory skills. For example, they are likely to understand that they need to have good organizational skills and reminders to help combat the decline in memory skills they face.

Older adults tend to overestimate the memory problems they experience on a daily basis. They seem to be more aware of their memory failures than younger adults and become more anxious about minor forgetfulness than younger adults do (Hoyer & Roodin, 2009). Researchers have found that in general older adults are as accurate as younger adults in monitoring the encoding and retrieval of information (Hertzog & Dixon, 2005), detecting errors when asked to proofread passages, and judging their own performance (Hargis & others, 2017). However, some aspects of monitoring information, such as source memory (discussed earlier in the chapter), decline in older adults (Isingrini, Perrotin, & Souchay, 2008).

Information Processing

1 The Information-Processing Approach

LG1 Explain the information-processing approach and its application to development.

The Information-Processing Approach and Its Application to Development

- The information-processing approach analyzes how individuals encode information, manipulate it, monitor it, and create strategies for handling it. Attention, memory, and thinking are involved in effective information processing. The computer has served as a model for how humans process information.
- In the information-processing approach, children's cognitive development results from their ability to overcome processing limitations by increasingly executing basic operations, expanding information-processing capacity, and acquiring new knowledge and strategies.
- According to Siegler, three important mechanisms of change in children's cognitive skills are encoding (how information gets into memory), automaticity (ability to process information with little or no effort), and strategy construction (creation of new procedures for processing information).
- Children's information processing is characterized by self-modification, and an important aspect of this self-modification involves metacognition—that is, knowing about knowing.

Speed of Processing Information

- Processing speed increases across childhood and adolescence, then slows in middle and late adulthood. However, strategies that people learn through experience can compensate to some degree for age-related decline in processing speed.

2 Attention

LG2 Define attention and outline its developmental changes.

What Is Attention?

- Attention is the focusing of mental resources. Four ways that people can allocate their attention are selective attention (focusing on a specific aspect of experience that is relevant while ignoring others that are irrelevant); divided attention (concentrating on more than one activity at the same time); sustained attention (maintaining attention to a selected stimulus for a prolonged period of time; also referred to as vigilance); and executive attention (involving action planning, allocating attention to goals, error detection and compensation, monitoring progress on tasks, and dealing with novel or difficult tasks).

Infancy

- Even newborns can fixate visually on a contour, but as they get older they scan a pattern more thoroughly. Attention in the first year of life is dominated by the orienting/investigative process. Attention in infancy often occurs through habituation and dishabituation. Joint attention plays an important role in infant development, especially in the infant's acquisition of language.

Childhood and Adolescence

- Salient stimuli tend to capture the attention of the preschooler. After 6 or 7 years of age, there is a shift to more cognitive control of attention. Selective attention improves through childhood and adolescence. Multitasking is an example of divided attention, and it can harm adolescents' attention when they are engaged in a challenging task.

Adulthood

- Attentional skills often are excellent in early adulthood. Older adults are generally less adept than younger adults at selective and divided attention.

3 Memory

LG3 Describe what memory is and how it changes through the life span.

What Is Memory?

- Memory is the retention of information over time. Psychologists study the processes of memory: how information is initially placed or encoded into memory, how it is retained or stored, and how it is found or retrieved for a certain purpose later. People construct and reconstruct their memories. Schema theory states that people mold memories to fit the information that already exists in their minds.

Infancy

- Infants as young as 2 to 6 months of age display implicit memory, which is memory without conscious recollection, as in memory of perceptual-motor skills. However, many experts believe that explicit memory, which is the conscious memory of facts and experiences, does not emerge until the second half of the first year of life.
- The hippocampus and frontal lobes of the brain are involved in development of memory in infancy. Older children and adults remember little if anything from the first three years of their lives.

Childhood

- One method of assessing short-term memory (the retention of information for up to 30 seconds, assuming there is no repetition of the information) is with a memory-span task on which there are substantial developmental changes through the childhood years.
- Working memory (a kind of "mental workbench" where individuals manipulate and assemble information when they make decisions, solve problems, and comprehend language) is linked to children's reading comprehension and problem solving.
- Increasing research interest has been shown in children's autobiographical memories and how these memories change developmentally.
- Young children can remember a great deal of information if they are given appropriate cues and prompts. Strategies can improve children's memory, and older children are more likely to use these than younger children. Imagery and elaboration are two important strategies. Knowledge is an important influence on memory.

Adulthood

- Younger adults have better episodic memory than older adults do. Older adults have more difficulty retrieving semantic information. Working memory decreases in older adults but has some plasticity. Explicit memory is more likely to decline in older adults than is implicit memory. Source memory—remembering where one learned something—declines with age. Controversy surrounds the question of whether prospective memory, which is remembering to do something in the future, declines as adults age.

4 Thinking

LG4 Characterize thinking and its developmental changes.

What Is Thinking?

- Thinking involves manipulating and transforming information in memory.

Infancy and Childhood

- Mandler argues that it is not until about 7 to 9 months of age that infants form conceptual categories, although we do not know precisely when concept formation begins.
- Infants' first concepts are broad. Over the first two years of life, these broad concepts gradually become more differentiated. Many infants and young children develop an intense interest in a particular category (or categories) of things.
- Advances in executive function, an umbrella-like concept that encompasses a number of higher-level cognitive processes linked to the development of the prefrontal cortex, occur in early childhood. Executive function involves managing one's thoughts to engage in goal-directed behavior and to exercise self-control. Executive function continued to improve in adolescence and emerging adulthood, then declines in late adulthood.
- Critical thinking involves thinking reflectively and productively as well as evaluating evidence. Recently, mindfulness training has been implemented to improve many aspects of children's development, including self-control.

Adolescence

- Key changes in information processing occur during adolescence, including processes involved in making decisions and exercising critical thinking.

Adulthood

- One aspect of cognition that may improve with aging is expertise. Many aspects of executive function decline in late adulthood, but individual differences occur as well.
- In the twentieth and twenty-first centuries, successive generations of older adults have been better educated, have had work experiences that included a stronger emphasis on cognitively oriented labor, and have been healthier. These cohort effects are linked to higher cognitive functioning.
- There has been increased interest in the cognitive neuroscience of aging, a scientific discipline that focuses on links between aging, the brain, and cognitive functioning. This field especially relies on fMRI and PET scans to assess brain functioning while individuals are engaging in cognitive tasks. One of the most consistent findings in this field is a decline in the functioning of specific regions in the prefrontal cortex in older adults and links between this decline and poorer performance on tasks that involve complex reasoning, working memory, and episodic memory.
- Some improvements in the cognitive vitality of older adults can be accomplished through cognitive and fitness training. However, such benefits have not been observed in all studies.

5 Metacognition

LG5 Define metacognition and summarize its developmental changes.

What Is Metacognition?

- Metacognition is thinking about thinking, or knowing about knowing. Metamemory is one aspect of metacognition that has been studied developmentally. By 5 to 6 years of age, children usually know that familiar items are easier to learn than unfamiliar ones and that short lists are easier to remember than long ones. By 7 to 8 years of age, children better appreciate the importance of cues for memory.

Theory of Mind

- Theory of mind is the awareness of one's own mental processes and the mental processes of others. Children begin to understand mental states involving perceptions, desires, and emotions at 2 to 3 years of age, and at 4 to 5 years of age they realize that people can have false beliefs. It is only beyond the early childhood years that children have a deepening appreciation of the mind itself rather than just understanding mental states. Autistic children have difficulty developing a theory of mind. As adolescents experience more complex social worlds, advances in their theory of mind skills occur in areas such as understanding another's intentions. For the most part, theory of mind skills remain intact during most of adulthood but decline in older adults.

Metacognition in Adolescence and Adulthood

- Adolescents have an increased capacity to monitor and manage resources to effectively meet the demands of a learning task, although there is considerable individual variation in metacognition during adolescence.
- Metacognition continues to improve in early adulthood, and many middle-aged individuals have accumulated considerable metacognitive knowledge. Older adults tend to overestimate their everyday memory problems.

preview

The concept of intelligence has generated many controversies, including debates about whether intelligence is more strongly influenced by heredity or by environment, whether there is cultural bias in intelligence testing, and whether intelligence tests are misused. We will explore these controversies, as well as the extent to which we have a single intelligence or multiple intelligences, the development of intelligence across the life span, and the extremes of intelligence and creativity.

1 The Concept of Intelligence

LG1 Explain the nature of intelligence.

- What Is Intelligence?
- Intelligence Tests
- Theories of Multiple Intelligences
- The Neuroscience of Intelligence

Intelligence is one of our most prized possessions. However, even the most intelligent people have not been able to agree on how to define and measure the concept of intelligence.

WHAT IS INTELLIGENCE?

What a piece of work is a man! How noble in reason! How infinite in faculty! In form, in moving, how express and admirable! In action how like an angel! In apprehension how like a god!

—WILLIAM SHAKESPEARE
English Playwright, 17th Century

What does the term *intelligence* mean to psychologists? Some experts describe intelligence as the ability to solve problems. Others describe it as the capacity to adapt and learn from experience. Still others argue that intelligence includes characteristics such as creativity and interpersonal skills.

The problem with intelligence is that, unlike height, weight, and age, intelligence cannot be directly measured. We can't peel back a person's scalp and see how much intelligence he or she has. We can evaluate intelligence only *indirectly* by studying and comparing the intelligent acts that people perform.

The primary components of intelligence are similar to the cognitive processes of thinking and memory that we discussed in the chapter on "Information Processing." The differences in how we described these cognitive processes in that chapter, and how we discuss intelligence, lie in the concepts of *individual differences* and assessment (Coyle, 2021; Kaufman, Schneider, & Kaufman, 2020). Individual differences are the stable, consistent ways in which people differ from one another (Schermer & Saklofske, 2021). Individual differences in intelligence generally have been measured by intelligence tests designed to tell us whether a person can reason better than others who have taken the test (Elkana & others, 2020).

How can intelligence be defined? **Intelligence** is the ability to solve problems and to adapt and learn from experiences. But even this broad definition doesn't satisfy everyone. As you will see shortly, Robert J. Sternberg (2020a, b; 2021a, b) proposes that practical know-how should be considered part of intelligence. In his view, intelligence involves weighing options carefully and acting judiciously, as well as developing strategies to improve shortcomings. Sternberg (2020a, b; 2021a, b) also recently described intelligence as the ability to adapt to, shape, and select environments. In adapting to the environment, if individuals find the environment suboptimal, they can change it to make it more suitable for their skills and desires.

Also, a definition of intelligence based on a theory such as Vygotsky's would have to include the ability to use the tools of the culture with help from more-skilled individuals. Because intelligence is such an abstract, broad concept, it is not surprising that there are so many different ways to define it.

developmental connection
Information Processing
The information-processing approach emphasizes how individuals manipulate information, monitor it, and create strategies for handling it. Connect to "Information Processing."

developmental connection
Social Contexts
Vygotsky's theory emphasizes the social contexts of learning and constructing knowledge through social interaction. Connect to "Cognitive Developmental Approaches."

intelligence The ability to solve problems and to adapt to and learn from experiences.

INTELLIGENCE TESTS

What types of intelligence tests are given to children and adults? What are some contributions and criticisms of intelligence tests?

The Binet Tests In 1904, the French Ministry of Education asked psychologist Alfred Binet to devise a method to determine which students would not profit from typical school instruction. Binet and his student Theophile Simon developed an intelligence test to fulfill this

request. The test consisted of 30 items ranging from the ability to touch one's nose or ear when asked to the ability to draw designs from memory and to define abstract concepts.

Binet stressed that the core of intelligence consists of complex cognitive processes such as memory, imagery, comprehension, and judgment. In addition, he noted that a developmental approach was crucial for understanding intelligence. He proposed that a child's intellectual ability increases with age. Therefore, he tested potential items and determined the age at which a typical child could answer them correctly. Thus, Binet developed the concept of **mental age (MA),** which is an individual's level of mental development relative to others. For an average child, MA scores correspond to *chronological age (CA)*, which is age from birth. A bright child has an MA considerably above CA; a child with a low level of intelligence has an MA considerably below CA.

The Binet test has been revised many times to incorporate advances in the understanding of intelligence and intelligence testing. Many revisions were carried out by Lewis Terman, who developed extensive norms and provided detailed, clear instructions for each problem on the test. Terman also applied a concept introduced by William Stern (1912), who coined the term **intelligence quotient (IQ)** to refer to an individual's mental age divided by chronological age, multiplied by 100: IQ = MA/CA × 100.

If a child's mental age, as measured by the Binet test, was the same as the child's chronological age, then the child's IQ score was 100. If the measured mental age was above chronological age, then the IQ score was greater than 100. If mental age was below chronological age, the IQ score was less than 100. Although this scoring system is no longer used, the term IQ is often still used to refer to a score on a standardized intelligence test.

In 2004, the test, now called the Stanford-Binet 5 (Stanford University is where the revisions have been done), was revised to analyze an individual's responses in five content areas: fluid reasoning, knowledge, quantitative reasoning, visual-spatial reasoning, and working memory. A general composite score also is obtained. Today the test is scored by comparing the test-taker's performance with the results achieved by other people of the same age. The average score is set at 100.

The current Stanford-Binet is given to individuals from age 2 through adulthood. It includes a wide variety of items, some requiring verbal responses, and others, nonverbal responses. For example, a 6-year-old is expected to complete the verbal task of defining at least six words, such as *orange* and *envelope*, and the nonverbal task of tracing a path through a maze. An adult with average intelligence is expected to define such words as *disproportionate* and *regard*, explain a proverb, and compare the concepts of idleness and laziness.

Over the years, the Stanford-Binet has been given to thousands of children and adults of different ages. By administering the test to large numbers of individuals selected at random from different parts of the United States, researchers have found that the scores approximate a normal distribution (see Figure 1). A **normal distribution** is a symmetrical, bell-shaped curve with a majority of the cases falling in the middle of the range of possible scores and few scores appearing toward the extremes of the range. The Stanford-Binet continues to be one of the most widely used individual tests of intelligence.

The Wechsler Scales

Besides the Stanford-Binet, the other most widely used intelligence tests are the Wechsler scales (Elkana & others, 2020). In 1939, David Wechsler introduced the first of his scales, designed for use with adults (Wechsler, 1939); the current edition

Alfred Binet constructed the first intelligence test after being asked to create a measure to determine which children could benefit from instruction in France's schools and which could not.
Universal History Archive/Getty Images

mental age (MA) An individual's level of mental development relative to that of others.

intelligence quotient (IQ) An individual's mental age divided by chronological age, multiplied by 100; devised in 1912 by William Stern.

normal distribution A symmetrical, bell-shaped curve with a majority of the cases falling in the middle of the possible range of scores and few scores appearing toward the extremes of the range.

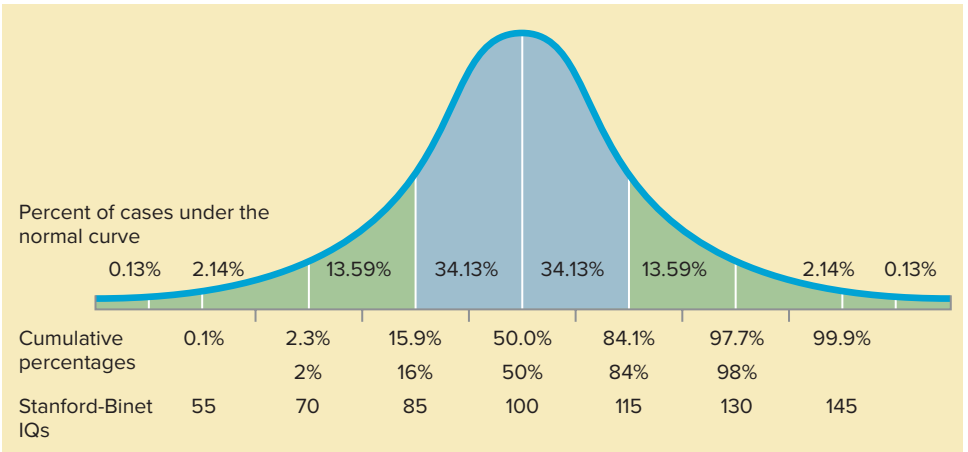

FIGURE 1

THE NORMAL CURVE AND STANFORD-BINET IQ SCORES. The distribution of IQ scores approximates a normal curve. Most of the population falls in the middle range of scores. Notice that extremely high and extremely low scores are very rare. Slightly more than two-thirds of the scores fall between 85 and 115. Only about 1 in 50 individuals has an IQ higher than 130, and only about 1 in 50 individuals has an IQ lower than 70.

Verbal Subscales

Similarities

A child must think logically and abstractly to answer a number of questions about how things might be similar.

Example: "In what way are a lion and a tiger alike?"

Comprehension

This subscale is designed to measure an individual's judgment and common sense.

Example: "What is the advantage of keeping money in a bank?"

Nonverbal Subscales

Block Design

A child must assemble a set of multicolored blocks to match designs that the examiner shows. Visual-motor coordination, perceptual organization, and the ability to visualize spatially are assessed.

Example: "Use the four blocks on the left to make the pattern on the right."

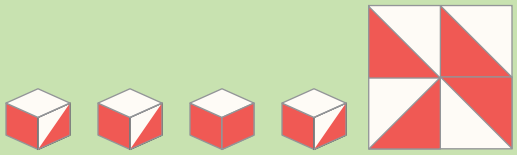

FIGURE **2**

SAMPLE SUBSCALES OF THE WECHSLER INTELLIGENCE SCALE FOR CHILDREN—FIFTH EDITION (WISC-V). The Wechsler includes 16 verbal and nonverbal subscales. Three of the subscales are shown here.
Source: Wechsler Intelligence Scale for Children® Fifth Edition (WISC-V), Upper Saddle River, NJ: Pearson Education, Inc., 2014.

is the Wechsler Adult Intelligence Scale–Fourth Edition (WAIS-IV). The Wechsler Intelligence Scale for Children–Fifth Edition (WISC-V) is designed for children and adolescents between the ages of 6 and 16 (Wechsler, 2014). The Wechsler Preschool and Primary Scale of Intelligence–Fourth Edition (WPPSI-IV) is appropriate for children from age 2 years 6 months to 7 years 7 months.

The WISC-V now not only provides an overall IQ score but also yields five composite scores (Verbal Comprehension, Working Memory, Processing Speed, Fluid Reasoning, and Visual Spatial) (Wright, 2020). These scores allow the examiner to quickly see whether the individual is strong or weak in different areas of intelligence (Canivez & others, 2020). The Wechsler scales also include 16 verbal and nonverbal subscales. Three of the Wechsler subscales are shown in Figure 2.

The Use and Misuse of Intelligence Tests Psychological tests are tools. As with all tools, their effectiveness depends on the knowledge, skill, and integrity of the user. A hammer can be used to build a beautiful kitchen cabinet or it can be used as a weapon of assault. Like a hammer, psychological tests can be used for positive purposes or they can be abused.

Intelligence tests have real-world applications as predictors of school performance, job success, and economic growth in a country (Mayer, 2020; Wai & Bailey, 2021). For example, scores on tests of general intelligence are substantially correlated with school grades and achievement test performance, both at the time of the test and years later (Brody, 2007). IQ in the sixth grade correlates about +.60 with the number of years of education the individual will eventually obtain (Jencks, 1979). Also, a recent study found that the collective IQ of a country's citizens was linked to its economic growth (Hafer, 2017).

Intelligence tests are moderately correlated with work performance (Lubinski, 2000). Individuals with higher scores on tests designed to measure general intelligence tend to get higher-paying, more prestigious jobs, and are more intrinsically satisfied with their jobs (Ganzach & Fried, 2012; Zagorsky, 2007). However, general IQ tests predict only 10 to 30 percent of the variation in job success, with the majority of job success due to motivation, education, and other factors (Sternberg, 2014). Further, the correlations between IQ and achievement decrease the longer people work at a job, presumably because as they gain more job experience they perform better (Hunt, 1995).

Thus, although there are correlations between IQ scores and academic achievement and occupational success, many other factors contribute to success in school and at work. These include the motivation to succeed, physical and mental health, and social skills (Sternberg, 2003).

The single number provided by many IQ tests can easily lead to false expectations about an individual (Rosnow & Rosenthal, 1996). Sweeping generalizations are too often made on the basis of an IQ score and can become self-fulfilling prophecies (Weinstein, 2004).

Even though they have limitations, tests of intelligence are among psychology's most widely used tools (Wright, 2020). To be effective, they should be used in conjunction with other information about an individual. For example, an intelligence test alone should not determine whether a child is placed in a special education or gifted class. The child's developmental history, medical background, performance in school, social competencies, and family experiences should be taken into account as well.

THEORIES OF MULTIPLE INTELLIGENCES

Is it more appropriate to think of intelligence as a general ability (*G*) or as a number of specific abilities (*s*)? The use of a single score to describe how people perform on intelligence tests implies that intelligence is a general ability, a single trait. Wechsler scales provide scores for a number of intellectual skills, as well as an overall score. Do people have some general mental ability that determines how they perform on all of these tests? Or is intelligence a label for a combination of several distinct abilities? And do conventional intelligence tests measure

everything that should be considered part of intelligence? Psychologists disagree about the answers to these questions.

Sternberg's Triarchic Theory Robert J. Sternberg (1986, 2004, 2010, 2015, 2018a, 2019a, b, 2020a, b, c, d, e, 2021a, b) notes that traditional IQ tests fail to measure some important dimensions of intelligence. Sternberg proposes a triarchic theory of intelligence involving three main types of intelligence: analytical, creative, and practical.

Sternberg developed the **triarchic theory of intelligence,** which states that intelligence comes in three forms: (1) *analytical intelligence,* which refers to the ability to analyze, judge, evaluate, compare, and contrast; (2) *creative intelligence,* which consists of the ability to create, design, invent, originate, and imagine; and (3) *practical intelligence,* which involves the ability to use, apply, implement, and put ideas into practice.

Sternberg (2021a, b) says that students with different triarchic patterns "look different" in school. Students with high analytical ability tend to be favored in conventional schooling. They often do well under direct instruction, in which the teacher lectures and gives students objective tests. They often are considered to be "smart" students who get good grades, show up in high-level tracks, do well on traditional tests of intelligence and the SAT, and later get admitted to competitive colleges.

In contrast, students who are high in creative intelligence often are not on the top rung of their class. Many teachers have specific expectations about how assignments should be done, and creatively intelligent students may not conform to those expectations. Instead of giving conformist answers, they give unique answers, for which they might get reprimanded or marked down. No teacher wants to discourage creativity, but Sternberg stresses that too often a teacher's desire to increase students' knowledge suppresses creative thinking.

Like students high in creative intelligence, children who are high in practical intelligence often do not relate well to the demands of school. However, many of these students do well outside the classroom's walls. They may have excellent social skills and good common sense. As adults, some become successful managers, entrepreneurs, or politicians in spite of having undistinguished school records.

Sternberg (2021a, b) emphasizes that successful intelligence involves an individual's ability to set and accomplish personally meaningful goals. A person does this by exploring and figuring out his or her strengths and weaknesses, then capitalizing on the strengths and correcting or improving on the weaknesses. An individual needs to analyze these strengths and weaknesses in the three domains of intelligence just discussed—analytical, creative, and practical. In addition, recently Sternberg has argued that a fourth domain—wisdom—needs to also be considered, especially in terms of doing the right thing and making ethical decisions that take into account the common good. Later in the chapter, we will discuss Sternberg's view of wisdom in greater depth.

Robert J. Sternberg, who developed the triarchic theory of intelligence.

Gardner's Theory of Multiple Intelligences According to Howard Gardner (1983, 1993, 2002, 2016), people have multiple intelligences, and IQ tests measure only a few of these. He argues that IQ tests measure verbal, math, and spatial aspects of intelligence while overlooking a number of other abilities. For evidence of the existence of multiple intelligences, Gardner uses information about the ways in which certain cognitive abilities survive particular types of brain damage. He also points to child prodigies and to some individuals with intellectual disability or autism who have an extraordinary skill in a particular domain. An example was portrayed by Dustin Hoffman in the movie *Rain Man*. Hoffman's character was autistic but had a remarkable computing ability. In one scene, he helped his brother successfully gamble in Las Vegas by keeping track of all the cards that had been played.

Gardner has proposed eight types of intelligence. They are described here, along with examples of the occupations in which they are regarded as strengths (Campbell, Campbell, & Dickinson, 2004):

- *Verbal*. The ability to think in words and use language to express meaning (occupations: authors, journalists, speakers)
- *Mathematical*. The ability to carry out mathematical operations (occupations: scientists, engineers, accountants)
- *Spatial*. The ability to think three-dimensionally (occupations: architects, artists, sailors)
- *Bodily-kinesthetic*. The ability to manipulate objects and be physically adept (occupations: surgeons, craftspeople, dancers, athletes)

Steve Hansen/The LIFE Images Collection/Getty Images

triarchic theory of intelligence Sternberg's theory that intelligence consists of analytical intelligence, creative intelligence, and practical intelligence.

- *Musical*. A sensitivity to pitch, melody, rhythm, and tone (occupations: composers, musicians, and sensitive listeners)
- *Interpersonal*. The ability to understand and effectively interact with others (occupations: successful teachers, mental health professionals)
- *Intrapersonal*. The ability to understand oneself (occupations: theologians, psychologists)
- *Naturalist*. The ability to observe patterns in nature and understand natural and human-made systems (occupations: farmers, botanists, ecologists, landscapers)

Recently, Gardner has considered adding a ninth type of intelligence to his list of multiple intelligences—existentialist, which involves exploring and finding meaning in life, especially regarding questions about life, death, and existence.

Gardner notes that each of the eight intelligences can be destroyed by brain damage, that each involves unique cognitive skills, and that each shows up in exaggerated fashion in the gifted and in individuals with intellectual disability or autism. According to Gardner, everyone has all of these intelligences but to varying degrees. As a result, we prefer to learn and process information in different ways. People perform best when they can apply their strong intelligences to the task at hand.

Emotional Intelligence Both Sternberg's and Gardner's theories include one or more categories related to social intelligence. In Sternberg's theory, the category is practical intelligence; in Gardner's theory, they are interpersonal intelligence and intrapersonal intelligence. Another theory that emphasizes interpersonal, intrapersonal, and practical aspects of intelligence involves **emotional intelligence,** a concept that has been popularized by Daniel Goleman (1995) in his book *Emotional Intelligence*. The concept of emotional intelligence was initially developed by Peter Salovey and John Mayer (1990), who define it as the ability to perceive and express emotion accurately and adaptively (such as taking the perspective of others), to understand emotion and emotional knowledge (such as understanding the roles that emotions play in friendship and marriage), to use feelings to facilitate thought (such as being in a positive mood, which is linked to creative thinking), and to manage emotions in oneself and others (such as being able to control one's anger).

There continues to be considerable interest in the concept of emotional intelligence (Dave & others 2021; Di Fabio & Saklofske, 2021; Romero-Mesa, Pelaez-Fernandez, & Extremera, 2021). One study revealed that abilities involving emotional intelligence were linked to academic achievement above and beyond cognitive and personality factors (Lanciano & Curci, 2014). Also, in a recent study of older adults, emotional intelligence was positively linked to cognitive functioning (Saad & others, 2021). And in a recent meta-analysis, emotional intelligence was the third best predictor of academic performance, following general intelligence and the personality trait of conscientiousness (MacCann & others, 2020). Critics argue that emotional intelligence broadens the concept of intelligence too far to be useful and has not been adequately assessed and researched.

emotional intelligence The ability to perceive and express emotions accurately and adaptively, to understand emotion and emotional knowledge, to use feelings to facilitate thought, and to manage emotions in oneself and others.

Gardner	Sternberg	Salovey/Mayer
Verbal Mathematical	Analytical	
Spatial Movement Musical	Creative	
Interpersonal Intrapersonal	Practical	Emotional
Naturalistic		

FIGURE **3**

COMPARING GARDNER'S, STERNBERG'S, AND SALOVEY/MAYER'S INTELLIGENCES.

Do People Have One or Many Intelligences? Figure 3 compares Gardner's, Sternberg's, and Salovey/Mayer's views of intelligence. Notice that Sternberg's view is unique in emphasizing creative intelligence and that Gardner's includes a number of types of intelligence that are not addressed by the other views. These theories of multiple intelligences have much to offer. They have stimulated us to think more broadly about what makes up people's intelligence and competence, and they have motivated educators to develop programs that instruct students in different domains (Kornhaber, 2020).

Theories of multiple intelligences have their critics (Hagmann-von Arx, Lemola, & Grob, 2018). Some argue that the research base to support these theories has not yet been developed. In particular, some critics say that Gardner's classification seems arbitrary. For example, if musical skills represent a type of intelligence, why don't we also refer to chess intelligence, prize-fighter intelligence, and so on?

A number of psychologists continue to support the concept of general intelligence (*G*). For example, in a recent survey of 102 experts on intelligence

around the world, most supported the concept of *G* (Rindermann, Becker, & Coyle, 2020). Studies have linked children's general intelligence with their self-control (Meldrum & others, 2017) and adolescents' IQs with engagement in health-promoting behaviors such as exercise, better diet, and not smoking in middle adulthood (Wraw & others, 2018). Higher IQ in adolescence also is associated with having a younger subjective age in late adulthood (Stephan & others, 2018).

One expert on intelligence, Nathan Brody (2007), argues that people who excel at one type of intellectual task are likely to excel in other intellectual tasks. Thus, individuals who do well at memorizing lists of digits are also likely to be good at solving verbal problems and spatial layout problems. This general intelligence includes abstract reasoning or thinking, the capacity to acquire knowledge, and problem-solving ability (Brody, 2000).

Advocates of the concept of general intelligence point to its accuracy in predicting school and job success. For example, scores on tests of general intelligence are substantially correlated with school grades and achievement test performance, both at the time of the test and years later (Sackett, Shewach, & Dahlke, 2020). For example, a research meta-analysis of 240 independent samples and more than 100,000 individuals found a correlation of +.54 between intelligence and school grades (Roth & others, 2015).

In sum, controversy still surrounds the issue of whether it is more accurate to conceptualize intelligence as a general ability, as specific abilities, or as both (Kornhaber, 2020). Sternberg (2021a, b) accepts that there is evidence to support the concept of general intelligence in the kinds of analytical tasks that traditional IQ tests assess, but he thinks that the range of intellectual tasks those tests measure is too narrow.

THE NEUROSCIENCE OF INTELLIGENCE

In the current era of extensive research on the brain, interest in the neurological underpinnings of intelligence has increased (Barbey, Karama, & Haier, 2021; Haier, 2020). Among the questions about the brain's role in intelligence that are being explored are these: Is having a bigger brain linked to higher intelligence? Is intelligence located in certain brain regions? Is the speed at which the brain processes information linked to intelligence?

Are individuals with bigger brains more intelligent than those with smaller brains? Studies using MRI scans to assess total brain volume indicate a moderate correlation (about 1.3 to 1.4) between brain size and intelligence (Lerch & others, 2017).

Might intelligence be linked to specific regions of the brain? Early consensus was that the frontal lobes are the likely location of intelligence. Today, some experts continue to emphasize that high-level thinking skills involved in intelligence are linked to the prefrontal cortex (Sternberg & Sternberg, 2017). However, other researchers have found that intelligence is distributed more widely across brain regions (Kundu & Risk, 2021). The most prominent finding from brain-imaging studies is that a distributed neural network involving the frontal and parietal lobes is related to higher intelligence (Haier, 2020) (see Figure 4). Albert Einstein's total brain size was average, but a region of his brain's parietal lobe that is very active in processing math and spatial information was 15 percent larger than average (Witelson, Kigar, & Harvey, 1999).

As technological advances allow closer study of the brain's functioning in coming decades, we are likely to see more specific conclusions about the brain's role in intelligence (Barbey, Karama, & Haier, 2021). As this research proceeds, keep in mind that both heredity and environment likely contribute to links between the brain and intelligence, including the connections we discussed between brain size and intelligence.

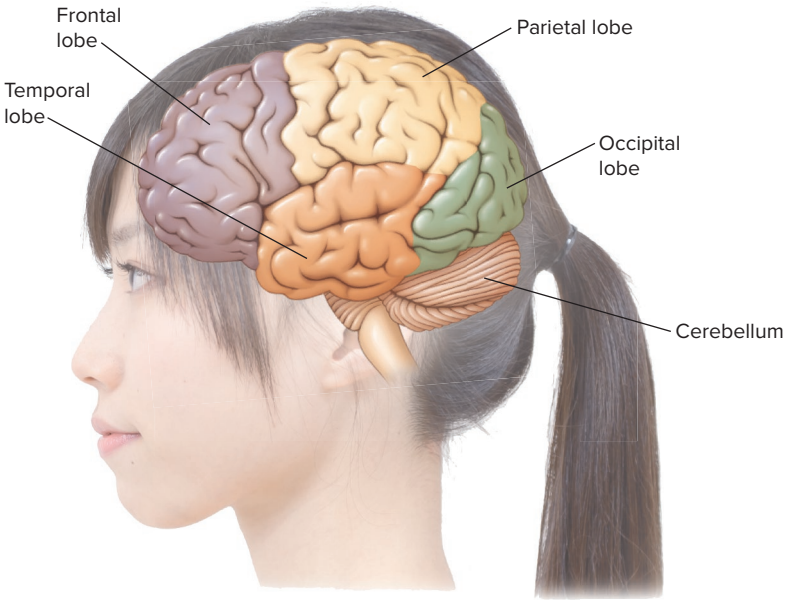

FIGURE **4**

INTELLIGENCE AND THE BRAIN. Researchers recently have found that a higher level of intelligence is linked to a distributed neural network in the frontal and parietal lobes. To a lesser extent than the frontal/parietal network, the temporal and occipital lobes, as well as the cerebellum, also have been found to have links to intelligence. The current consensus is that intelligence is likely to be distributed across brain regions rather than being localized in a specific region such as the frontal lobes.

2 Controversies and Group Comparisons

LG2 Outline key controversies about differences in IQ scores.

The Influence of Heredity and Environment

Group Comparisons and Issues

We have seen that intelligence is a slippery concept with competing definitions, tests, and theories. It is not surprising, therefore, that attempts to understand the concept of intelligence are surrounded by controversy. In some cases, the controversies arise over comparisons of the intelligence of different groups, such as people from different cultural or ethnic backgrounds.

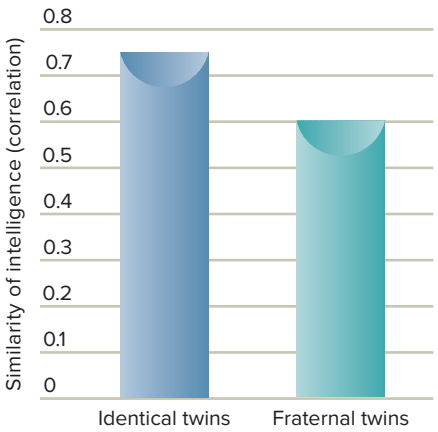

FIGURE **5**

CORRELATION BETWEEN INTELLIGENCE TEST SCORES AND TWIN STATUS. The graph represents a summary of research findings that have compared the intelligence test scores of identical and fraternal twins. An approximate .15 difference has been found, with a higher correlation for identical twins (.75) and a lower correlation for fraternal twins (.60).

THE INFLUENCE OF HEREDITY AND ENVIRONMENT

An area of considerable debate in the study of intelligence centers on the extent to which intelligence is influenced by genetics (nature) versus the extent to which it is influenced by environment (nurture) (Sternberg, 2021a, b; Tan & Grigorenko, 2020). It is difficult to tease apart these influences, but psychologists keep trying to unravel them.

Genetic Influences To what degree do our genes make us smart? Researchers have attempted to answer this question by comparing the IQ similarity of identical twins (who have the same genes) with that of fraternal twins (who do not have matching genes). Some scientists argue that there is a strong genetic component to intelligence (Kamatani, 2021). However, a research review found that the difference in the average correlations for identical and fraternal twins was not very high—only .15 (Grigorenko, 2000) (see Figure 5). And genetic influences may be more influential in some aspects of life than others. For example, in one study genes were much more strongly linked to scientific achievement than to artistic achievement (de Manzano & Ullen, 2018).

Have scientists been able to pinpoint specific genes that are linked to intelligence? A research review concluded that there may be more than 1,000 genes that affect intelligence, each possibly having a small influence on an individual's intelligence (Davies & others, 2011). However, researchers have not been able to identify the specific genes that contribute to intelligence (Zhao, Kong, & Qu, 2014).

Environmental Influences Although genetic endowment influences a person's intellectual ability, the environmental experiences of children and adults do make a difference (Mayer, 2020). In one study, researchers found that how much parents communicated with their children during the first three years of their lives was correlated with the children's

Stanford-Binet IQ scores at age 3 (Hart & Risley, 1995). The more parents communicated with their children, the higher the children's IQs were. And research by Richard Nisbett and his colleagues (2012) supported the importance of environmental influences on intelligence: A 12- to 18-point increase in IQ was found when children had been adopted from low-income families into middle- and upper-income families.

Schooling also influences intelligence (Mayer, 2020). The biggest effects have been found when large groups of children received no formal education for an extended period, resulting in lower intelligence. In a recent Danish study, IQ test scores were positively associated with educational attainment in early and middle adulthood (Hegelund & others, 2020). Also in this study, individuals with low intelligence in childhood benefited the most from education.

Students in an elementary school in South Africa. *How might schooling influence the development of children's intelligence?*
Owen Franken/Corbis Documentary/Getty Images

Recent research indicates that intelligence varies across countries and is linked to various environmental conditions in the countries (Flynn & Sternberg, 2020). For example, in a recent study of 22 countries (including Argentina, China, France, India, Peru, Turkey, and the United States), variations in intelligence across countries were linked to income, educational attainment, health, and socioeconomic status (Lynn, Fuerst, & Kirkegaard, 2018).

Another possible effect of education can be seen in rapidly increasing IQ test scores around the world (Flynn, 2007, 2013, 2018, 2020). IQ scores have been rising so quickly that a high percentage of people regarded as having average intelligence in the early 1900s would be considered below average in intelligence today (see Figure 6). If a representative sample of today's children took the Stanford-Binet test used in 1932, about one-fourth would be defined as very superior, a label usually accorded to less than 3 percent of the population. A meta-analysis of 53 studies since 1972 found that IQ scores have been rising about 3 points per decade since that year and that the increase in IQ scores does not seem to be diminishing (Trahan & others, 2014). This worldwide increase in intelligence test scores over a short time frame is called the *Flynn effect* after the researcher who discovered it—James Flynn (2007, 2013, 2018, 2020).

Although rising intelligence test scores have been found in most countries in which cohort effects on intelligence have been assessed, a decrease in intelligence test scores has been found in Scandinavian countries (Finland, Norway, Denmark, and Norway) beginning about 1995 (Dutton & Lynn, 2013; Ronnlund & others, 2013). Explanations of the IQ decline focus on technological advances, such as television, smartphones, and social media, as well as weakening educational systems. However, IQ gains continue to occur in the United States and most developing countries (Flynn & Shayer, 2018; Flynn & Sternberg, 2020). For example, in a recent study in the Sudanese capital of Khartoum in Africa, IQ scores increased by 10 points from 2004 to 2016 (Dutton & others, 2018). And in another study, IQ scores increased slightly more than 5 points from 2003 to 2018 in Romania (Gunnesch-Luca & Iliescu, 2020).

Because the change in test scores has taken place in a relatively short period of time, it can't be due to heredity. Rather, it might result from environmental factors such as the exploding quantities of information to which people are exposed and the much higher percentage of the population who receive education (Flynn, 2020; Flynn & Sternberg, 2020).

Might increasing scores on IQ tests in a country be linked to subsequent economic benefits for that country? In a recent study of 28 countries, IQ increases in a country were

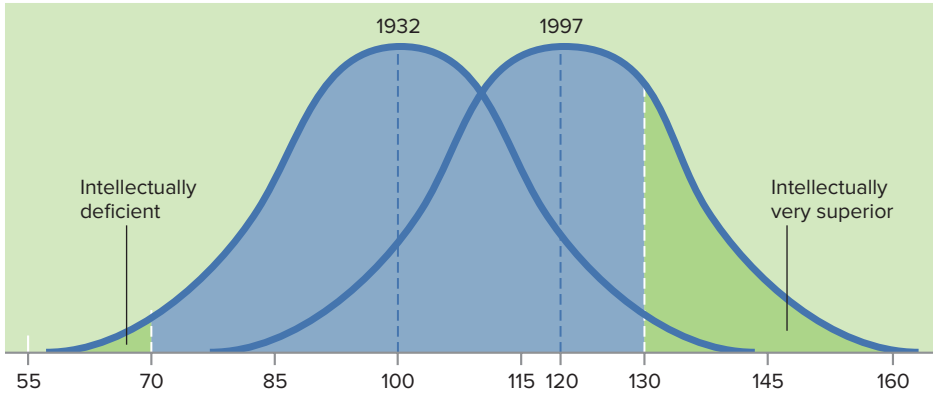

FIGURE 6

THE INCREASE IN IQ SCORES FROM 1932 TO 1997. As measured by the Stanford-Binet test, American children seem to be getting smarter. Scores of a group tested in 1932 fell along a bell-shaped curve with half below 100 and half above. Studies show that if children took that same test today, half would score above 120 on the 1932 scale. Very few of them would score in the "intellectually deficient" end on the left side, and about one-fourth would rank in the "very superior" range. Researchers are continuing to find support for the Flynn effect in the 21st century (Laciga & Cigler, 2017; Shenk, 2017).

Can Early Intervention in the Lives of Children Growing Up in Impoverished Circumstances Improve Their Intelligence?

Courtesy Dr. Craig Ramey

Craig Ramey
Key Points:
- children living in poverty
- early intervention
- improving intelligence

Each morning a young mother waited with her child for the bus that would take the child to school. The child was only 2 months old, and "school" was an experimental program at the University of North Carolina at Chapel Hill. There the child experienced a number of interventions designed to improve her intellectual development—everything from bright objects dangled in front of her eyes while she was a baby to language instruction and counting activities when she was a toddler (Wickelgren, 1999). The child's mother had an IQ of 40 and could not read signs or determine how much change she should receive from a cashier. Her grandmother had a similarly low IQ.

Today, at age 20, the child's IQ measures 80 points higher than her mother's did when the child was 2 months old. Not everyone agrees that IQ can be affected this extensively by early interventions, but it is clear that environment can make a substantial difference in a child's intelligence. As behavior geneticist Robert Plomin (1999) has said, even something that is highly heritable (like intelligence) may be malleable through interventions.

The child we just described was part of the Abecedarian Intervention program at the University of North Carolina at Chapel Hill conducted by Craig Ramey and his associates (Campbell, 2007; Campbell & others, 2012; Ramey & Campbell, 1984; Ramey & Ramey, 1998). They randomly assigned 111 young children from low-income, poorly educated families to either an intervention group, which received full-time, year-round child care along with medical and social work services, or a control group, which received medical and social benefits but no child care. The child-care program included gamelike learning activities aimed at improving language, motor, social, and cognitive skills.

The success of the program in improving IQ was evident by the time the children were 3 years of age. At that age, the experimental group showed normal IQs averaging 101, a 17-point advantage over the control group. Follow-up results suggest that the effects are long-lasting. More than a decade later, at age 15, children from the intervention group still maintained an IQ advantage of 5 points over the control-group children (97.7 to 92.6) (Campbell, 2007; Campbell & others, 2001; Ramey, Ramey, & Lanzi, 2001). They also did better on standardized tests of reading and math, and they were less likely to be held back a year in school. Also, the greatest IQ gains were made by the children whose mothers had especially low IQs—below 70. At age 15, these children showed a 10-point IQ advantage over a group of children whose mothers' IQs were below 70 but who had not experienced the child-care intervention. In one analysis of the Abecedarian intervention project, at age 30 the individuals who had experienced the early intervention had attained more years of education, but the intervention had not led to any benefits involving social adjustment or criminal activity (Campbell & others, 2012).

The Abecedarian intervention study supports other research that has found prevention/intervention to be more effective than later remediation in improving the lives of children growing up in impoverished circumstances (Phillips & Lowenstein, 2011). Thus, it is important to consider the types of environments children experience as they develop, both in the general population and in especially challenging contexts.

The highest-risk children often benefit the most cognitively when they experience early interventions.

—Craig Ramey
Contemporary Psychologist, Georgetown University

associated with higher GDP (gross domestic product, a key indicator of economic prosperity) 5, 10, 15, and 20 years later (Rindermann & Becker, 2018).

Keep in mind that environmental influences are complex. Growing up with all the "advantages," for example, does not guarantee success. Children from wealthy families may have easy access to excellent schools, books, travel, and tutoring, but they may take such opportunities for granted and fail to develop the motivation to learn and achieve. In the same way, "poor" or "disadvantaged" does not automatically equal "doomed." Researchers increasingly are exploring ways to improve the early environments of children who are at risk for impoverished intelligence (Schiariti, Simeonsson, & Hall, 2021). The emphasis is on prevention rather than remediation. Many low-income parents have difficulty providing an intellectually stimulating environment for their children (Shuey & Leventhal, 2019). Programs that educate parents to be more sensitive caregivers and better teachers, while providing support services such as quality child-care programs, can make a difference in a child's intellectual development (Bredekamp, 2020). In a two-year intervention study with families living in poverty, maternal scaffolding and positive home stimulation improved young children's intellectual functioning (Obradovic & others, 2016).

Can we actually measure environmental influences on intelligence? To read more, see the *Connecting with Research* interlude.

In sum, there is a consensus among psychologists that both heredity and environment influence intelligence (Grigorenko & Burenkova, 2020; Tan & Grigorenko, 2020). This consensus reflects the nature-nurture issue, which was highlighted in the chapter titled "Introduction." Recall that the nature-nurture issue focuses on the extent to which development is influenced by nature (heredity) and nurture (environment). Although psychologists agree that intelligence is the product of both nature and nurture, there is still disagreement about how strongly each factor influences intelligence (Anderson & Holmes, 2021; Flynn & Sternberg, 2020).

developmental **connection**

Nature and Nurture

The epigenetic approach emphasizes the ongoing, bidirectional interaction of heredity and environment. Connect to "Biological Beginnings."

GROUP COMPARISONS AND ISSUES

Group comparisons in intelligence can involve cultures and ethnic groups. We begin by discussing cross-cultural comparisons and then explore the influence of cultural bias in testing.

Cross-Cultural Comparisons Cultures vary in the way they describe what it means to be intelligent (Sternberg, 2020f). People in Western cultures tend to view intelligence in terms of reasoning and thinking skills, whereas people in Eastern cultures see intelligence as a way for members of a community to successfully engage in social roles (Nisbett, 2003).

In a study of the Luo culture in rural Kenya, children who scored highly on a test of knowledge about medicinal herbs—a measure of practical intelligence—tended to score poorly on tests of academic intelligence (Sternberg & others, 2001). These results indicated that practical and academic intelligence can develop independently and may even conflict with each other. They also suggest that the values of a culture may influence the direction in which a child develops. In a cross-cultural context, then, intelligence depends a great deal on environment (Sternberg, 2020f).

Cultural Bias in Testing Many of the early intelligence tests were culturally biased, favoring people who were from urban rather than rural environments, middle socioeconomic status rather than low socioeconomic status, and non-Latinx White rather than African American ethnicity (Provenzo, 2002). Also, members of minority groups who do not speak English or who speak nonstandard English are at a disadvantage in trying to understand questions framed in standard English.

One potential influence on intelligence test performance is **stereotype threat**, a fear that one's behavior might confirm a negative stereotype about one's group (Konopka & others, 2021; Moreau, 2021). Researchers have confirmed the existence of stereotype threat (Drace, Korlat, & Dokic, 2020). For example, when African Americans take an intelligence test, they may experience anxiety about confirming an old stereotype that Blacks are "intellectually inferior." Many studies support the existence of stereotype threat (Crosby, 2021). For example, African American students do more poorly on standardized tests if they perceive that they are being evaluated. If they think the test doesn't count, they perform as well as White students (Aronson, 2002). However, some critics argue that the extent to which stereotype threat explains the testing gap has been exaggerated (Sackett, Borneman, & Connelly, 2009).

Researchers have developed **culture-fair tests,** which are intelligence tests that are designed to avoid cultural bias. Two types of culture-fair tests have been developed. The first includes questions that are familiar to people from all socioeconomic and ethnic backgrounds. For example, a child might be asked how a bird and a dog are different, on the assumption that virtually all children are familiar with birds and dogs. The second type of culture-fair test contains no verbal questions.

Why is it so hard to create culture-fair tests? Most tests tend to reflect what the dominant culture thinks is important (Ang, Ng, & Rockstuhl, 2020). If tests have time limits, these will bias the test against groups that are not concerned with time. If languages differ, the same words might have different meanings for different language groups. Even pictures can produce bias, because some cultures have less experience than others with drawings and photographs (Anastasi & Urbina, 1996). Within the same culture, different groups could have different attitudes, values, and motivation, and this could affect their performance on intelligence tests. Items that ask why buildings should be made of brick are biased against children who have little or no experience with brick houses. Questions about railroads, furnaces, seasons of the year, distances between cities, and so on can be biased against groups who have less experience than others with these contexts. Because of such difficulties, Robert Sternberg (2020f) concludes that there are no culture-fair tests, but only culture-reduced tests.

stereotype threat Anxiety regarding whether one's behavior might confirm a negative stereotype about one's group.

culture-fair tests Intelligence tests that are designed to avoid cultural bias.

Ethnic Comparisons In the United States, children from African American and Latinx families score below children from non-Latinx White families on standardized intelligence tests (Yeung, 2012). On average, African American schoolchildren score 10 to 15 points lower on standardized intelligence tests than non-Latinx White schoolchildren do (Brody, 2000). These are *average scores*, however. About 15 to 25 percent of African American schoolchildren score higher than half of non-Latinx White schoolchildren do. The reason is that the distribution of scores for African Americans and non-Latinx Whites overlap.

As African Americans have gained social, economic, and educational opportunities, the gap between African Americans and non-Latinx Whites on standardized intelligence tests has begun to narrow. A research review concluded that the IQ gap between African Americans and non-Latinx Whites has decreased considerably in recent decades (Nisbett & others, 2012). This gap especially narrows in college, where African American and non-Latinx White students often experience more similar environments than during the elementary and high school years (Myerson & others, 1998). Also, when children from disadvantaged African American families are adopted into more advantaged middle-socioeconomic-status families, their scores on intelligence tests more closely resemble national averages for middle-socioeconomic-status children than for lower-socioeconomic-status children (Scarr & Weinberg, 1983). Further, a study using the Stanford Binet Intelligence Scales found no differences in overall intellectual ability between non-Latinx White and African American preschool children when the children were matched on age, gender, and parental education level (Dale & others, 2014). Nonetheless, a research analysis concluded that the underrepresentation of African Americans in STEM (science, technology, engineering, and math) subjects and careers is linked to practitioners' expectations that members of this group have less innate talent for the subject matter than non-Latinx Whites do (Leslie & others, 2015).

3 The Development of Intelligence

LG3 Discuss the development of intelligence across the life span.

Tests of Infant Intelligence | Stability and Change in Intelligence Through Adolescence | Intelligence in Adulthood

How can the intelligence of infants be assessed? Is intelligence stable throughout childhood? Does intelligence decline in older adults, and if so, when and by how much? These are some of the questions we will explore as we examine the development of intelligence.

TESTS OF INFANT INTELLIGENCE

The infant-testing movement grew out of the tradition of IQ testing. However, tests that assess infants are necessarily less verbal than IQ tests for older children. Tests for infants contain far more items related to perceptual-motor development. They also include measures of social

Toosje Thyssen Van Beveren, Infant Assessment Specialist

Toosje Thyssen Van Beveren is a developmental psychologist at the University of Texas Medical Center in Dallas. She has a master's degree in child clinical psychology and a Ph.D. in human development. Currently, Van Beveren is involved in a 12-week program called New Connections, which is a comprehensive intervention for young children who were affected by substance abuse prenatally and for their caregivers.

In the New Connections program, Van Beveren assesses infants' developmental status and progress. She might refer the infants to a speech, physical, or occupational therapist and monitor the infants' progress during therapeutic interventions. Van Beveren trains the program staff and encourages them to use the exercises she recommends. She also discusses the child's problems with the primary caregivers, suggests activities, and assists them in enrolling infants in appropriate programs.

During her graduate work at the University of Texas at Dallas, Van Beveren was author John Santrock's teaching assistant in his undergraduate course on life-span development for four years. As a teaching assistant, she attended classes, graded exams, counseled students, and occasionally gave lectures. Each semester, Van Beveren returns to give a lecture on prenatal development and infancy. She also teaches several courses each semester in the psychology department at UT–Dallas. In Van Beveren's words, "My days are busy and full. The work is often challenging. There are some disappointments, but mostly the work is enormously gratifying."

interaction. To read about the work of one infant assessment specialist, see the *Connecting with Careers* profile.

The widely used **Bayley Scales of Infant Development** were developed by Nancy Bayley (1969) to assess infant behavior and predict later development. The current version, Bayley-III, has five scales: cognitive, language, motor, socio-emotional, and adaptive (Bayley, 2006). The first three scales are administered directly to the infant, while the latter two are questionnaires given to the caregiver. The Bayley-III also is more appropriate for use in clinical settings than the two previous editions (Gullion & others, 2019).

Bayley Scales of Infant Development Widely used scales, developed by Nancy Bayley, for assessing infant development. The current version, the Bayley-III, has five scales: cognitive, language, motor, socio-emotional, and adaptive; the first three are administered to the infant, the latter two to the caregiver.

How should a 6-month-old perform on the Bayley cognitive scale? The 6-month-old infant should be able to vocalize pleasure and displeasure, persistently search for objects that are just outside immediate reach, and approach a mirror that is placed in front of the infant by the examiner. By 12 months of age, the infant should be able to inhibit behavior when commanded to do so, imitate words the examiner says (such as *Mama*), and respond to simple requests (such as "Take a drink").

The increasing interest in infant development has produced many new measures, especially tasks that evaluate the ways infants process information (Blankenship & others, 2019; Hayne & Herbert, 2021). The Fagan Test of Infant Intelligence is increasingly being used (Fagan, 1992). This test focuses on the infant's ability to process information in ways such as encoding the attributes of objects, detecting similarities and differences between objects, forming mental representations, and retrieving these representations. For example, it measures the amount of time babies look at a new object compared with the amount of time they spend looking at a familiar object.

Items in the Bayley-III Scales of Infant Development.
Amy Kiley Photography

Unlike the Bayley scales, the Fagan test is correlated with measures of intelligence in older children. In fact, evidence is accumulating that measures of habituation and dishabituation are linked to intelligence in childhood, adolescence, and even adulthood. For example, one study

revealed that habituation assessed at 3 or 6 months of age was linked to verbal skills and intelligence assessed at 32 months of age (Domsch, Lohaus, & Thomas, 2009). Another study found that selective attention to novelty at 6 to 12 months was positively correlated with intelligence at 21 years of age (Fagan, Holland, & Wheeler, 2007). And a longitudinal study revealed that scores in four information-processing domains (attention, processing speed, memory, and representational competence) assessed in infancy and early childhood were linked to general intelligence scores on the Wechsler Intelligence Scale for Children–III assessed at 11 years of age (Rose & others, 2012).

Also, a longitudinal study found that developmental milestones at 24 months of age were strongly linked to IQ at 5 to 6 years of age, but those milestones at 4, 8, and 12 months were only slightly associated with IQ at 5 to 6 years (Peyre & others, 2017). Of the four developmental milestones (language, gross motor skills, fine motor skills, and socialization), early language skills were the best predictor of IQ. Further, early language skills were linked to intelligence in children who had an IQ lower than 70 (intellectual disability) (predicted from 8 months of age) and higher than 130 (gifted) (predicted from 12 months of age) at 5 to 6 years of age. And in another study, developmental milestones assessed at 3 years of age were linked to scores on the Wechsler Adult Intelligence Scale at 20 to 34 years of age, with the strongest associations occurring for the early developmental milestones of language and social interaction (Flensborg-Madsen & Mortensen, 2018).

It is important, however, not to go too far and think that connections between cognitive development in early infancy and later cognitive development are so strong that no discontinuity takes place. Significant changes in cognitive development occur after infancy.

STABILITY AND CHANGE IN INTELLIGENCE THROUGH ADOLESCENCE

A longitudinal study examined the intelligence of 200 children from 12 months (using the Bayley scales) to 4 years old (using the Stanford-Binet test) (Blaga & others, 2009). The results indicated considerable stability from late infancy through the preschool years.

An early study examined correlations between IQ test scores at a number of different ages (Honzik, MacFarlane, & Allen, 1948). There was a strong relation between IQ scores obtained at the ages of 6, 8, and 9 and IQ scores obtained at the age of 10. For example, the correlation between IQ at the age of 8 and IQ at the age of 10 was .88. The correlation between IQ at the age of 9 and IQ at the age of 10 was .90. These figures show a high degree of consistency in IQ scores obtained in these years. The correlation between IQ in the preadolescent years and IQ at the age of 18 was slightly lower but still statistically significant. For example, the correlation between IQ at the age of 10 and IQ at the age of 18 was .70. Also, in a recent study, intelligence showed considerable stability across four developmental periods: infancy, early childhood, middle and late childhood, and adolescence (Yu & others, 2018). As expected, though, when there was a greater time lapse between tests (infancy to adolescence, for example) IQ scores showed less stability than they did when testing occurred in adjacent time frames (infancy to early childhood, for example).

Much of what has been said so far about the stability of intelligence has been based on measures of groups of individuals. The stability of intelligence also can be evaluated through studies of individuals. Robert McCall and his associates (McCall, Applebaum, & Hogarty, 1973) studied 140 children between the ages of 2½ and 17. They found that the average range of IQ scores was more than 28 points. The scores of one out of three children changed by as much as 40 points.

What can we conclude about stability and changes in intelligence during childhood? Intelligence test scores can fluctuate dramatically across the childhood years, indicating that intelligence is not as stable as the original intelligence theorists envisioned. Children are adaptive beings. They have the capacity for intellectual change, but they do not become entirely new intelligent beings. In a sense, children's intelligence changes but remains connected with earlier points in development.

developmental **connection**

Life-Span Perspective

The stability-change issue is a major focus of study in the field of life-span development. Connect to "Introduction."

INTELLIGENCE IN ADULTHOOD

Does intelligence increase or decrease in adulthood? Might older adults have greater wisdom than younger adults? These are among the questions that we will explore in this section.

Fluid and Crystallized Intelligence John Horn emphasizes that some abilities increase throughout the life span, whereas others steadily decline from middle adulthood onward (Horn, 2007; Horn & Donaldson, 1980). Horn argues that **crystallized intelligence,** an individual's accumulated information and verbal skills, continues to increase throughout the life span. However, he notes that **fluid intelligence,** the ability to reason effectively, begins to decline in middle adulthood (see Figure 7).

Horn's data were collected in a cross-sectional manner. A *cross-sectional study* assesses individuals of different ages at the same point in time. For example, a cross-sectional study might assess the intelligence of groups of 40-, 50-, and 60-year-olds in one evaluation, such as in 1990. The average 40-year-old and the average 60-year-old were born in eras that offered different economic and educational opportunities. For example, as the 60-year-olds grew up they likely had fewer educational opportunities, which probably influenced their scores on intelligence tests. Thus, if we find differences between 40- and 60-year-olds on intelligence tests when they are assessed cross-sectionally, these differences might be due to cohort effects (attributes reflecting an individual's time of birth or generation rather than his or her age) such as educational differences rather than simply reflecting the person's age.

In contrast, in a *longitudinal study*, the same individuals are studied over a period of time. Thus, a longitudinal study of intelligence in middle adulthood might consist of giving the same intelligence test to the same individuals when they are 40, when they are 50, and when they are 60 years of age. Whether data are collected cross-sectionally or longitudinally makes a difference in what is found about intellectual decline.

In a recent study of 24- to 93-year-olds, everyday problem solving performance increased from early to middle adulthood but began to show a decline at about 50 years of age (Chen, Hertzog, & Park, 2017). In this study, fluid intelligence predicted everyday problem solving performance in young adults but with increasing age, crystallized intelligence became a better predictor. Also, in a recent large-scale study, fluid intelligence declined in individuals 65 years of age and older but not in those 45 to 60 years old (Cornelis & others, 2019).

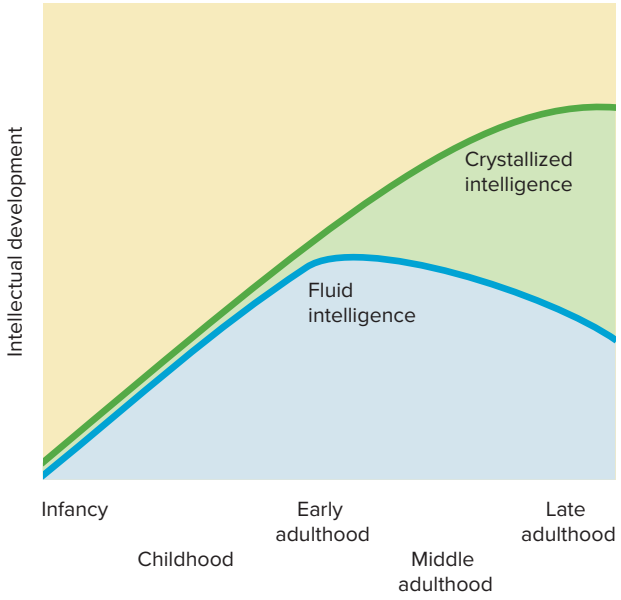

FIGURE **7**

FLUID AND CRYSTALLIZED INTELLECTUAL DEVELOPMENT ACROSS THE LIFE SPAN. According to Horn, crystallized intelligence (based on cumulative learning experiences) increases throughout the life span, but fluid intelligence (reasoning effectively) steadily declines from middle adulthood onward.

crystallized intelligence An individual's accumulated information and verbal skills, which continues to increase with age.

fluid intelligence The ability to reason effectively.

The Seattle Longitudinal Study K. Warner Schaie (1983, 1996, 2005, 2010, 2016) has conducted an extensive study of intellectual abilities during adulthood. Five hundred individuals initially were tested in 1956, and new waves of participants are added periodically. The main mental abilities tested in the Seattle Longitudinal Study are as follows:

- *Verbal comprehension* (ability to understand ideas expressed in words)
- *Verbal memory* (ability to encode and recall meaningful language units, such as a list of words)
- *Numeric ability* (ability to perform simple mathematical computations such as addition, subtraction, and multiplication)
- *Spatial orientation* (ability to visualize and mentally rotate stimuli in two- and three-dimensional space)
- *Inductive reasoning* (ability to recognize and understand patterns and relationships in a problem and use this understanding to solve other instances of the problem)
- *Perceptual speed* (ability to quickly and accurately make simple discriminations in visual stimuli)

K. Warner Schaie (*right*) is one of the leading pioneers in the field of life-span development. He is shown here with two older adults who are actively using their cognitive skills. Schaie's research represents one of the most thorough examinations of how individuals develop and change as they go through the adult years.
Courtesy of Dr. K. Warner Schaie

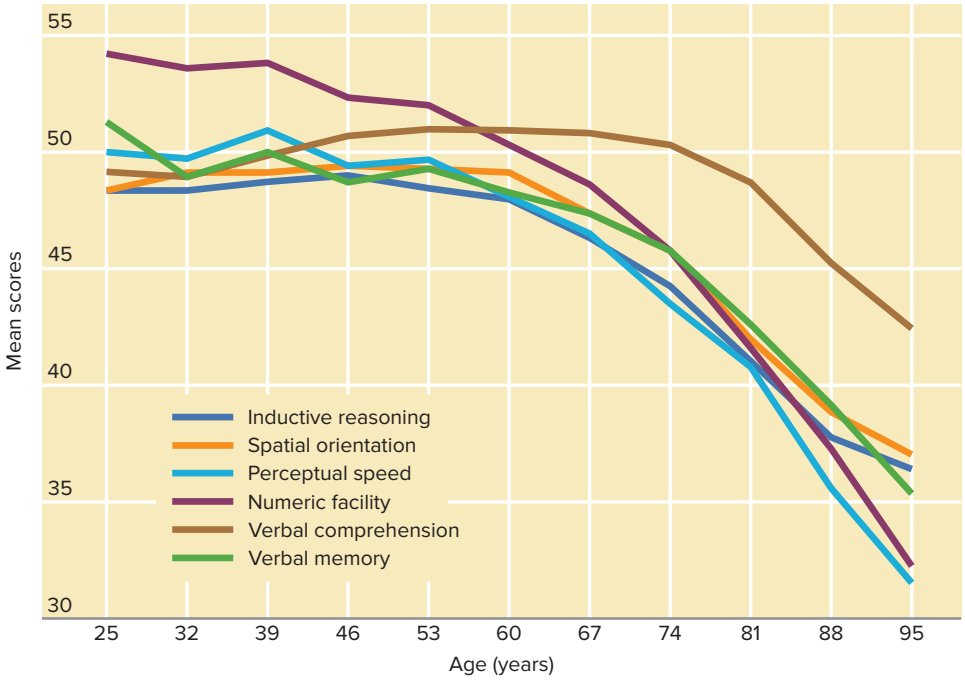
As shown in Figure 8, the highest level of functioning for four of the six intellectual abilities occurred during middle adulthood (Schaie, 2013). For both women and men, performance on verbal comprehension, verbal memory, inductive reasoning, and spatial orientation peaked in middle age. Only two of the six abilities—numeric facility and perceptual speed—declined in middle age.

Notice in Figure 8 that the declines in functioning for most cognitive abilities began to steepen in the sixties, although the

FIGURE 8

LONGITUDINAL CHANGES IN SIX INTELLECTUAL ABILITIES FROM AGE 25 TO AGE 95.

Source: Schaie, K.W. "Longitudinal Changes in Six Intellectual Abilities from Age 25 to Age 95." *Developmental Influences on Intelligence: The Seattle Longitudinal Study,* 2e, rev, 2013, 162.



decline in verbal comprehension did not steepen until the mid-seventies. From the mid-seventies through the mid-nineties, all cognitive abilities showed considerable decline. When Schaie (1994) assessed intellectual abilities both cross-sectionally and longitudinally, he found that decline was more likely to occur in the cross-sectional than in the longitudinal assessments. For example, as shown in Figure 9, when assessed longitudinally, inductive reasoning ability increased until toward the end of middle adulthood and then began to show a slight decline. In contrast, when assessed cross-sectionally, inductive reasoning showed a consistent decline during middle adulthood. For the participants in the Seattle Longitudinal Study, middle age was a time of peak performance both for some aspects of crystallized intelligence (verbal comprehension) and for fluid intelligence (spatial orientation and inductive reasoning). Also recall our discussion in the "Introduction" chapter that some researchers have found that cross-sectional studies indicate more than 90 percent of cognitive decline in aging is due to a slowing of processing speed, whereas longitudinal studies reveal that 20 percent or less of cognitive decline is due to slowing of processing speed (MacDonald & Stawski, 2015, 2016).

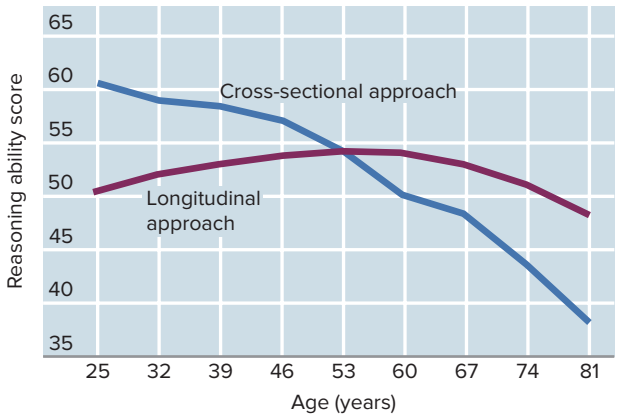


FIGURE 9

CROSS-SECTIONAL AND LONGITUDINAL COMPARISONS OF INDUCTIVE REASONING ABILITY ACROSS ADULTHOOD. In Schaie's research, the cross-sectional approach revealed declining scores with age; the longitudinal approach showed a slight rise of scores in middle adulthood and only a slight decline beginning in the early part of late adulthood.

Some researchers disagree with Schaie that middle adulthood is a time when the level of functioning in a number of cognitive domains is maintained or even increases (Finch, 2009). For example, Timothy Salthouse (2012, 2016, 2019) has argued that cross-sectional research on aging and cognitive functioning should not be dismissed and that this research indicates reasoning, memory, spatial visualization, and processing speed begin declining in early adulthood and show further decline in the fifties. Salthouse (2012) does agree that cognitive functioning involving accumulated knowledge, such as vocabulary and general information, does not show early age-related decline but rather continues to increase at least until 60 years of age. Salthouse (2012) has emphasized that a lower level of cognitive functioning in middle adulthood is likely due to age-related neurobiological decline. Salthouse (2014, 2019) has argued that a main reason for different trends in longitudinal and cross-sectional comparisons of cognitive functioning is that prior experience taking a test results in higher scores the next time the test is taken.

Schaie (2016) continues to emphasize that longitudinal studies hold the key to determining age-related changes in cognitive functioning and that middle age is the time during which many cognitive skills actually peak. In

the next decade, expanding research on age-related neurobiological changes and their possible links to cognitive skills should further refine our knowledge about age-related cognitive functioning in the adult years (Haier, 2020).

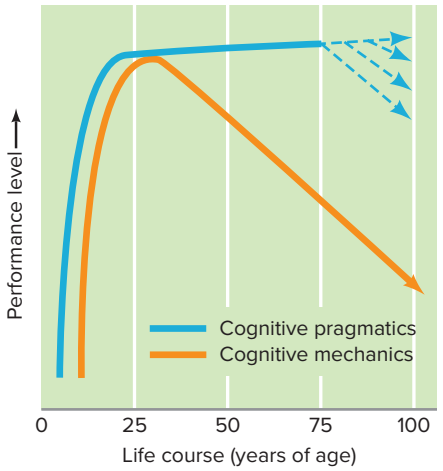

FIGURE 10

THEORIZED AGE CHANGES IN COGNITIVE MECHANICS AND COGNITIVE PRAGMATICS. Baltes argues that cognitive mechanics declines during aging, whereas cognitive pragmatics does not, at least for many people until they become very old. Cognitive mechanics has a biological/genetic foundation; cognitive pragmatics has an experiential/cultural foundation. The broken lines from 75 to 100 years of age indicate possible individual variations in cognitive pragmatics.

Cognitive Mechanics and Cognitive Pragmatics

Paul Baltes (1993, 2003) clarified the distinction between those aspects of the mind that decline with advancing age and those that remain stable or even improve. He makes a distinction between "cognitive mechanics" and "cognitive pragmatics" that extends the fluid/crystallized intelligence conceptualization described earlier:

- **Cognitive mechanics** is the "hardware" of the mind and reflects the neurophysiological architecture of the brain developed through evolution. Cognitive mechanics consists of the speed and accuracy of the processes involved in sensory input, attention, visual and motor memory, discrimination, comparison, and categorization. Because of the strong influence of biology, heredity, and health on cognitive mechanics, a decline with aging is likely.
- **Cognitive pragmatics** encompasses the culture-based "software programs" of the mind. Cognitive pragmatics includes reading and writing skills, language comprehension, educational qualifications, and professional skills, as well as self-knowledge and life skills that help us to master or cope with life. Because of the strong influence of culture on cognitive pragmatics, ongoing improvement can continue to take place. Thus, although cognitive mechanics may decline in old age, cognitive pragmatics may actually improve during this period (see Figure 10).

The distinction between cognitive mechanics and cognitive pragmatics is similar to the one between fluid (mechanics) and crystallized (pragmatics) intelligence that was described earlier. Indeed, the similarity is so strong that some experts now use the terms *fluid mechanics* and *crystallized pragmatics* to describe cognitive aging patterns (Lovden & Lindenberger, 2007).

developmental **connection**

Culture

In Baltes' view, for older adults the benefits of evolutionary selection decrease while the need for culture increases. Connect to "Biological Beginnings."

Wisdom

As you just saw, Baltes stresses that wisdom is an important aspect of cognitive pragmatics. Baltes and his colleagues (2006) define **wisdom** as expert knowledge about the practical aspects of life that permits excellent judgment about important matters. This practical knowledge involves exceptional insight about human development and life matters, good judgment, and understanding of how to cope with difficult life problems. Thus, wisdom, more than standard conceptions of intelligence, focuses on life's pragmatic concerns and human conditions (Aldwin, Igarashi, & Levenson, 2020; Wang & others, 2021).

In regard to wisdom, Baltes and his colleagues (Baltes & Kunzmann, 2004; Baltes & Smith, 2008) have reached the following conclusions:

- High levels of wisdom are rare. Few people, including older adults, attain a high level of wisdom. That only a small percentage of adults show wisdom supports the contention that it requires experience, practice, or complex skills.
- Factors other than age are critical for wisdom to develop to a high level. For example, certain life experiences, such as being trained and working in a field concerned with difficult life problems and having wisdom-enhancing mentors, contribute to higher levels of wisdom. Also, people higher in wisdom have values that are more likely to consider the welfare of others than to focus exclusively on their own happiness.
- Personality-related factors, such as openness to experience, generativity, and creativity, are better predictors of wisdom than cognitive factors such as intelligence.

Robert J. Sternberg (1998, 2019b) has proposed the **balance theory of wisdom**, which states that wisdom consists of using one's intelligence, creativity, common sense, and

cognitive mechanics The "hardware" of the mind, reflecting the neurophysiological architecture of the brain as developed through evolution. Cognitive mechanics involves the speed and accuracy of the processes involving sensory input, visual and motor memory, discrimination, comparison, and categorization.

cognitive pragmatics The culture-based "software" of the mind. Cognitive pragmatics includes reading and writing skills, language comprehension, educational qualifications, professional skills, and the self-knowledge and life skills that help us to master or cope with life.

wisdom Expert knowledge about the practical aspects of life that permits excellent judgment about important matters.

balance theory of wisdom Sternberg's theory that wisdom consists of using one's intelligence, creativity, common sense, and knowledge in a balanced, ethical manner. Individuals should apply their wisdom in a balanced way across intrapersonal, interpersonal, and extrapersonal contexts to promote the common good.

Older adults might not be as quick with their thoughts or behavior as younger people, but wisdom may be an entirely different matter. This older man shares the wisdom of his experience with his granddaughter. *How is wisdom described by life-span developmentalists?*
Johnny Greig/Getty Images

knowledge in a balanced, ethical manner. Individuals should apply their wisdom in a balanced way across intrapersonal (one's identity, for example), interpersonal (being caring and kind to others, for example), and extrapersonal (contributing in positive ways to one's community, for example) contexts. To become wise, he believes individuals need to apply practical knowledge in dealing with problems. For Sternberg, wisdom is about doing the right thing, especially when confronted with difficult decisions. In his view, if you look at people like Martin Luther King and Mother Teresa and compare them with Adolf Hitler and Joseph Stalin, they likely did not differ much in IQ but differed a great deal in their wisdom.

Other researchers, such as Igor Grossman (Grossman & others, 2020) and Judith Gluck (2020), have proposed a view that is close to Sternberg's view. In their perspective, wisdom involves being aware of your perspectives and beliefs in relation to others' and being motivated to attain some common good for a larger group, such as one's family, an institution, or even an entire nation. They believe that metacognitive thinking with a moral grounding is a critical factor in achieving this wisdom.

An increasing number of research studies have focused on the developmental aspects of wisdom at different points in life (Igarashi, Levenson, & Aldwin, 2018). For example, a recent study explored wisdom and meaning as important developments in emerging adulthood (Webster & others, 2018). In this study, researchers found that the search for and presence of meaning was linked to wisdom, which was assessed on the basis of five components: critical life experiences, reminiscence/reflectiveness, openness to experience, emotional regulation, and humor. Also, a recent study found that self-reflective exploratory processing of difficult life experiences (meaning-making and personal growth) was linked to a higher level of wisdom (Westrate & Gluck, 2017). Another recent study found that the personality trait of openness to experience in early adulthood predicted wisdom 60 years later (Ardelt, Gerlach, & Vaillant, 2018). Also in this study, wisdom in late adulthood could be traced back to experiences and characteristics at different points in development: a supportive childhood, adolescent competence, emotional stability in young adulthood, and generativity in middle adulthood. And a recent study indicated that wisdom peaked in midlife, with education especially linked to a higher level of wisdom (Ardelt, Pridgen, & Nutter-Pridgen, 2018).

4 The Extremes of Intelligence and Creativity

LG4 Describe the characteristics of intellectual disability, giftedness, and creativity.

Intellectual Disability | Giftedness | Creativity

Intellectual disability and intellectual giftedness are the extremes of intelligence. Often intelligence tests are used to identify exceptional individuals. We will explore the nature of intellectual disability and giftedness, then examine how creativity differs from intelligence.

INTELLECTUAL DISABILITY

The most distinctive feature of intellectual disability (formerly called mental retardation) is inadequate intellectual functioning (Elliott & Resing, 2020). Long before formal tests were developed to assess intelligence, individuals with an intellectual disability were identified by a lack of age-appropriate skills in learning and caring for themselves. Once intelligence tests were developed, they were used to identify the degree of intellectual disability. But of two individuals with an intellectual disability who have the same low IQ, one might be married, employed, and involved in the community and the other might require constant supervision in an institution. Such differences in social competence led psychologists to include deficits in adaptive behavior in their definition of intellectual disability (Smith & others, 2018).

intellectual disability A condition of limited mental ability in which an individual has a low IQ, usually below 70 on a traditional test of intelligence, and has difficulty adapting to the demands of everyday life.

Intellectual disability is a condition of limited mental ability in which the individual (1) has a low IQ, usually below 70 on a traditional intelligence test; (2) has difficulty adapting to the demands of everyday life; and (3) first exhibits these characteristics by age 18. The age limit is included in the definition of intellectual disability because, for example, we don't usually think of a college student who suffers massive brain damage in a car accident, resulting in an IQ of 60, as having an "intellectual disability." The low IQ and low adaptiveness should be evident in childhood, not after normal functioning is interrupted by damage of some form. About 5 million Americans fit this definition of intellectual disability.

There are several ways to define degrees of intellectual disability (Hallahan, Kauffman, & Pullen, 2019). Most school systems use the classifications shown in Figure 11, in which IQ scores categorize intellectual disability as mild, moderate, severe, or profound.

Note that a large majority of individuals diagnosed with an intellectual disability fit into the mild category. However, these categories are not perfect predictors of functioning. A different classification is based on the degree of support required for a person with an intellectual

Type of Intellectual Disability	IQ Range	Percentage of Individuals with an Intellectual Disability
Mild	55 to 70	89
Moderate	40 to 54	6
Severe	25 to 39	4
Profound	Below 25	1

FIGURE **11**
CLASSIFICATION OF INTELLECTUAL DISABILITY BASED ON IQ.

Classification of Intellectual Disability	Level of Support Needed
Intermittent	Supports are provided "as needed." The individual may need episodic or short-term support during life-span transitions (such as job loss or acute medical crisis). Intermittent supports may be low or high intensity when provided.
Limited	Supports are intense and relatively consistent over time. They are time-limited but not intermittent, require fewer staff members, and cost less than more intense supports. These supports likely will be needed for adaptation to the changes involved in the school-to-adult period.
Extensive	Supports are characterized by regular involvement (for example, daily) in at least some setting (such as home or work) and are not time-limited (for example, extended home-living support).
Pervasive	Supports are constant, very intense, and are provided across settings. They may be of a life-sustaining nature. These supports typically involve more staff members and intrusiveness than the other support categories.

FIGURE **12**

CLASSIFICATION OF INTELLECTUAL DISABILITY BASED ON LEVELS OF SUPPORT NEEDED.

disability to function at the highest level. As shown in Figure 12, these categories of support are intermittent, limited, extensive, and pervasive.

Some cases of intellectual disability have an organic cause. *Organic intellectual disability* describes a genetic disorder or a lower level of intellectual functioning caused by brain damage (Mir & Kuchay, 2019). Down syndrome is one form of organic intellectual disability, and it occurs when an extra chromosome is present. Other causes of organic intellectual disability include fragile X syndrome, an abnormality in the X chromosome; prenatal malformation; metabolic disorders; and diseases that affect the brain. Most people who suffer from organic intellectual disability have IQs between 0 and 50.

When no evidence of organic brain damage can be found, cases are labeled *cultural-familial intellectual disability*. Individuals with this type of disability have IQs between 55 and 70. Psychologists suspect that this type of disability often stems from growing up in a below-average intellectual environment. Children with this type of disability can be identified in schools, where they often fail, need tangible rewards (candy rather than praise), and are highly sensitive to what others expect of them. However, as adults, they are usually not noticeable, perhaps because adult settings don't tax their cognitive skills as sorely. It may also be that their intelligence increases as they move toward adulthood.

giftedness Having above-average intelligence (an IQ of 130 or higher) and/or superior talent for something.

GIFTEDNESS

There have always been people whose abilities and accomplishments outshine those of others—the whiz kid in class, the star athlete, the natural musician. People who are **gifted** have high intelligence or superior talent of some kind. An IQ of 130 is often used as the low threshold for giftedness, although this figure is arbitrary. Programs for the gifted in most school systems select children who have intellectual superiority and academic aptitude (Elliott & Resing, 2020). They tend to overlook children who are talented in the arts or athletics or who have other special aptitudes, including their passion and sense of destiny (Beghetto, 2019). Estimates vary but indicate that approximately 6 to 10 percent of U.S. students are classified as gifted (National Association for Gifted Children, 2020). This percentage is likely conservative because it focuses more on children who are gifted intellectually and academically, often failing to include those who are gifted in creative thinking or the visual and performing arts (Ford, 2012).

Until recently, giftedness and emotional distress were thought to go hand-in-hand. Virginia Woolf, Sir Isaac Newton, Vincent van Gogh, Anne Sexton, Socrates, and Sylvia Plath all had emotional problems. However, these individuals are the exception rather than the rule. In general, no connection between giftedness and mental disorder has been found. Research supports the conclusion that gifted people tend to be more mature, to have fewer emotional problems than others, and to grow up in a positive family climate (Feldhusen, 1999). One study revealed that parents and teachers identified elementary schoolchildren who are not gifted as having more emotional and behavioral risks than children who are gifted (Eklund & others, 2015). In this study, when children who are gifted did have problems, they were more likely to be internalized problems such as anxiety and depression than externalized problems such as acting out and high levels of aggression.

Characteristics of Children Who Are Gifted Aside from their abilities, do children who are gifted have distinctive characteristics? Lewis Terman (1925) conducted an extensive study of 1,500 children whose Stanford-Binet IQ scores averaged 150. Contrary to the popular myth that children who are gifted are maladjusted, Terman found that they were socially well adjusted.

Ellen Winner (1996) described three criteria that characterize gifted children, whether in art, music, or academic domains:

1. *Precocity*. Gifted children are precocious. They begin to master an area earlier than their peers. Learning in their domain is more effortless for them than for ordinary children. In most instances, these gifted children are precocious because they have an inborn high ability.
2. *Marching to their own drummer*. Gifted children learn in a qualitatively different way from ordinary children. For one thing, they need minimal help from adults to learn. In many cases, they resist explicit instruction. They also often make discoveries on their own and solve problems in unique ways.
3. *A passion to master*. Gifted children are driven to understand the domain in which they have high ability. They display an intense, obsessive interest and an ability to focus. They do not need to be pushed by their parents. They motivate themselves, says Winner.

A fourth area in which gifted children excel involves *information-processing skills*. Researchers have found that children who are gifted learn at a faster pace, process information more rapidly, are better at reasoning, use superior strategies, and monitor their understanding better than their nongifted counterparts (Ambrose & Sternberg, 2016).

In his most recent view of giftedness, Sternberg (2018b) argues that a high IQ and intelligence should not be isolated from other key aspects of an individual, such as creativity and wisdom. He especially emphasizes that when intelligence is assessed, wisdom also needs to be assessed.

Life Course of the Gifted As a 10-year-old, Alexandra Nechita (born in 1985) was described as a child prodigy. She paints quickly and impulsively on large canvases, some as large as 5 feet by 9 feet. It is not unusual for her to complete several of these large paintings in a week's time. Her paintings sell for up to $100,000 apiece. When she was only 2 years of age, Alexandra colored in coloring books for hours. She had no interest in dolls or friends. Once she started school, she would start painting as soon as she got home. And she continues to paint as an adult—relentlessly and passionately. It is, she says, what she loves to do. Recently, Alexandra completed a degree in Fine Arts at UCLA.

Is giftedness, like Alexandra Nechita's artistic talent and the children with profoundly superior math and verbal skills just described, a product of heredity or of environment? Likely both (Duggan & Friedman, 2014; Johnson & Bouchard, 2014). Individuals who are gifted recall that they had signs of high ability in a specific area at a very young age, prior to or at the beginning of formal training (Howe & others, 1995). This suggests the importance of innate ability in giftedness. However, researchers also have found that individuals with world-class status in the arts, mathematics, science, and sports all report strong family support and years of training and practice (Bloom, 1985). Deliberate practice is an important characteristic of individuals who become experts in a specific domain. For example, in one study, the best musicians engaged in twice as much deliberate practice over their lives as the least successful ones did (Ericsson, Krampe, & Tesch-Romer, 1993).

Do gifted children become gifted and highly creative adults? In Terman's research on children with superior IQs, the children typically became experts in a well-established domain, such as medicine, law, or business. However, they did not become major creators (Winner, 2000). That is, they did not create a new domain or revolutionize an existing domain.

One reason that some gifted children do not become gifted adults is that they often have been pushed too hard by overzealous parents and teachers. As a result, they lose their intrinsic (internal) motivation (Winner, 1996, 2006). As adolescents, they may ask themselves, "Who am I doing this for?" If they are achieving in an effort to please others rather than themselves, they may not want to do it anymore. Another reason that gifted children do not become gifted adults is that the criteria for giftedness change—as an adult, an individual has to actually do something special to be labeled gifted.

Domain-Specific Giftedness Individuals who are highly gifted are typically not gifted in many domains, and research on giftedness increasingly focuses on domain-specific developmental trajectories (Reis & Renzulli, 2020). During the childhood years, the domains in which individuals are gifted usually emerge. Thus, at some point in childhood, a person who is destined to become a gifted artist or a gifted mathematician begins to show expertise in that

Margaret (Peg) Cagle with some of the gifted seventh- and eighth-grade math students she teaches at Lawrence Middle School in Chatsworth, California. Cagle especially advocates challenging gifted students to take intellectual risks. To encourage collaboration, she often has students work together in groups of four, and frequently tutors students during lunch hour. As 13-year-old Madeline Lewis commented, "If I don't get it one way, she'll explain it another and talk to you about it and show you until you do get it." Cagle says it is important to be passionate about teaching math and open up a world for students that shows them how beautiful learning math can be (Wong Briggs, 2007, p. 6D).
Scott Buschman

domain. Regarding domain-specific giftedness, software genius Bill Gates (1998), the founder of Microsoft and one of the world's richest persons, commented that when you are good at something you may need to resist the urge to think that you will be good at everything. Gates says that because he has been so successful at software development, people expect him to be brilliant in other domains in which he is far from being a genius.

Education of Children Who Are Gifted An increasing number of experts argue that the education of gifted children in the United States requires a significant overhaul (Reis & Renzulli, 2020). Consider the titles of the following books and reports: *Genius Denied: How to Stop Wasting Our Brightest Young Minds* (Davidson & Davidson, 2004) and *A Nation Deceived: How Schools Hold Back America's Brightest Students* (Colangelo, Assouline, & Gross, 2004).

Gifted children who are underchallenged can become disruptive, skip classes, and lose interest in achieving. Sometimes these children just disappear into the woodwork, becoming passive and apathetic toward school. It is extremely important for teachers to challenge children who are gifted to establish high expectations for their own performance (Reis & Renzulli, 2020).

Some educators conclude that the inadequate education of children who are gifted has been compounded by policies established under the federal government's No Child Left Behind Act, which sought to raise the achievement level of students who were not doing well in school at the expense of enriching the education of children who were gifted (Clark, 2008). A number of experts argue that too often children who are gifted are socially isolated and underchallenged in the classroom (Karnes & Stephens, 2008). It is not unusual for them to be ostracized and labeled "nerds" or "geeks." Ellen Winner (1996, 2006) concludes that a child who is truly gifted often is the only child in the room who does not have the opportunity to learn with students of like ability.

Many eminent adults report that school was a negative experience for them, that they were bored and sometimes knew more than their teachers did (Bloom, 1985). Winner stresses that American education will benefit when standards are raised for all children. When some children are still underchallenged, she recommends that they be allowed to attend advanced classes in their domain of exceptional ability, such as allowing some especially precocious middle school students to take college classes in their area of expertise. For example, Bill Gates took college math classes and hacked a computer security system at 13; Yo-Yo Ma, a famous cellist, graduated from high school at 15 and attended Juilliard School of Music in New York City.

A final concern proposed by Donna Ford (2015a, b) is that African American, Latinx, and Native American children are underrepresented in gifted programs. Much of the underrepresentation involves the lower test scores for these children compared with non-Latinx White and Asian American children, which may be due to a number of reasons such as test bias and fewer opportunities to develop language skills such as vocabulary and comprehension (Ford, 2015a, b).

A young Bill Gates, founder of Microsoft and now one of the world's richest persons. Like many highly gifted students, Gates was not especially fond of school. He hacked a computer security system when he was 13 and as a high school student, he was allowed to take some college math classes. He dropped out of Harvard University and began developing a plan for what was to become Microsoft Corporation. *What are some ways that schools can enrich the education of such highly talented students as Gates to make it a more challenging, interesting, and meaningful experience?*
Joe McNally/Hulton Archive/Getty Images

CREATIVITY

We have encountered the term "creative" on several occasions in our discussion of giftedness. What does it mean to be creative? **Creativity** is the ability to think about something in novel and unusual ways and to come up with unique, good solutions to problems.

Intelligence and creativity are not the same thing (Kaufman & Sternberg, 2021). Most creative people are quite intelligent, but the reverse is not necessarily true. Many highly intelligent people (as measured by high scores on conventional tests of intelligence) are not very creative. Many highly intelligent people are also highly productive, but their output is not necessarily novel (Sternberg, 2020c).

Why don't IQ scores predict creativity? Creativity requires divergent thinking (Guilford, 1967; Roberts & others, 2021). **Divergent thinking** produces many answers to the same question. In contrast, conventional intelligence tests require **convergent thinking.** For example, a typical question on a conventional intelligence test is "How many quarters will you get in return for 60 dimes?" There is only one correct answer to this question. In contrast, a question such as "What image comes to mind when you hear the phrase 'sitting alone in a dark room'?" has many possible answers; it calls for divergent thinking.

One study examined the divergent thinking of 1-year-olds and their parents (Hoicka & others, 2016). In this study, the creativity of the 1-year-olds was associated with the creativity of their parents. How did researchers assess divergent thinking in 1-year-old children? A task called the Unusual Box Test was used, in which children play with a colorful box equipped with strings, hoops, stairs, ledges, and such, next to five novel objects. Their divergent thinking is determined by the number of different action/box combinations the children generate.

Thus, creative individuals defy the crowd, resisting merely thinking or doing what others are (Sternberg, 2021c). Instead, they go off in their own direction, motivated to develop novel ideas.

Steps in the Creative Process The creative process has often been described as a five-step sequence:

1. *Preparation*. You become immersed in a problem or an issue that interests you and arouses your curiosity.
2. *Incubation*. You churn ideas around in your head. This is the point at which you are likely to make some unusual connections in your thinking.
3. *Insight*. You experience the "Aha!" moment when all of the pieces of the puzzle seem to fit together.
4. *Evaluation*. Now you must decide whether the idea is valuable and worth pursuing. Is the idea really novel or is it obvious?
5. *Elaboration*. This final step often covers the longest span of time and requires the hardest work. This is what the famous twentieth-century American inventor Thomas Edison was talking about when he said that creativity is 1 percent inspiration and 99 percent perspiration. Elaboration may require a great deal of perspiration.

Mihaly Csikszentmihalyi (pronounced ME-high CHICK-sent-me-high-ee) (1996) notes that this five-step sequence provides a helpful framework for thinking about how creative ideas are developed. However, he argues that creative people don't always go through the steps in a linear sequence. For example, elaboration is often interrupted by periods of incubation. Fresh insights may appear during incubation, evaluation, and elaboration. And insight might take years or only a few hours. Sometimes the creative idea consists of one deep insight. Other times it's a series of small ones.

Creativity in Schools A special concern is that children's creative thinking appears to be declining. A study of approximately 300,000 U.S. children and adults found that creativity scores rose until 1990, but since then have been steadily declining (Kim, 2010). Among the likely causes of the creativity decline are the number of hours U.S. children spend watching TV, interacting on social media, and playing video games instead of engaging in creative activities, as well as the lack of emphasis on creative thinking skills in schools (Beghetto, 2019). Some countries, though, are placing increasing emphasis on stimulating creative thinking in schools (Lubart & others, 2021). For example, historically, creative thinking has typically been discouraged in Chinese schools. However, Chinese educators are now encouraging teachers to spend more classroom time on creative activities (Plucker, 2010).

An important teaching goal is to help students become more creative (Kaufman & Sternberg, 2021). Teachers need to recognize that students will show more creativity in some domains than in others (Plucker, Karwowski, & Kaufman, 2020). A student who shows creative thinking skills in mathematics may not exhibit these skills in art, for example.

Strategies for increasing children's creative thinking include the following:

- *Encourage brainstorming*. **Brainstorming** is a technique in which people are encouraged to come up with creative ideas in a group, play off each other's ideas, and say practically whatever comes to mind that seems relevant to a particular issue (Sawyer, 2019). Participants are usually told to hold off from criticizing others' ideas at least until the end of the brainstorming session.
- *Provide environments that stimulate creativity*. Some environments nourish creativity, while others inhibit it (Kaufman & Sternberg, 2021). Parents and teachers who encourage creativity often rely on children's natural curiosity. They provide exercises and activities that stimulate children to find insightful solutions to problems, rather than ask a lot of questions that require rote answers (Beghetto, 2021; Reis & Renzulli, 2020). Teachers also encourage creativity by taking students on field trips to locations where creativity is

creativity The ability to think in novel and unusual ways and to come up with unique solutions to problems.

divergent thinking Thinking that produces many answers to the same question; characteristic of creativity.

convergent thinking Thinking that produces one correct answer; this is the kind of thinking required by conventional intelligence tests.

brainstorming Technique in which individuals are encouraged to come up with creative ideas in a group, play off each other's ideas, and say practically whatever comes to mind that is relevant to a particular issue.

What are some good strategies for guiding children to think more creatively?
Ariel Skelley/Blend Images LLC

valued. Science, discovery, and children's museums offer rich opportunities to stimulate creativity.

- *Don't overcontrol students*. Teresa Amabile (2018) says that telling children exactly how to do things leaves them feeling that originality is a mistake and exploration is a waste of time. If, instead of dictating which activities they should engage in, you let children select their interests and you support their inclinations, you will be less likely to destroy their natural curiosity (Hennessey, 2021).
- *Encourage internal motivation*. Excessive use of prizes, such as gold stars, money, or toys, can stifle creativity by undermining the intrinsic pleasure students derive from creative activities. Creative children's motivation is the satisfaction generated by the work itself. Competition for prizes and formal evaluations often undermine intrinsic motivation and creativity (Hennessey, 2021). However, material rewards should not be eliminated altogether.
- *Build children's confidence*. To expand children's creativity, encourage them to believe in their own ability to create something innovative and worthwhile. Building children's confidence in their creative skills aligns with Bandura's (2010a, 2012) concept of self-efficacy—the belief that one can master a situation and produce positive outcomes.
- *Guide children to be persistent and delay gratification*. Most highly successful creative products take years to develop. Most creative individuals work on ideas and projects for months and years without being rewarded for their efforts (Sternberg, 2020c).
- *Encourage children to take intellectual risks*. Creative individuals take intellectual risks and seek to discover or invent something that has never before been discovered or invented (Sternberg, 2021c). They risk spending extensive time on an idea or project that may not work. Creative people are not afraid of failing or getting something wrong.
- *Introduce children to creative people*. Teachers can invite creative people to their classrooms and ask them to describe what helps them become creative or to demonstrate their creative skills. Writers, poets, musicians, scientists, and many others can bring their props and productions to the class, turning it into a theater for stimulating students' creativity.

To find out about steps you can take to live a more creative life, see the *Connecting Development to Life* interlude.

Changes in Adulthood At the age of 30, Thomas Edison invented the phonograph, Hans Christian Andersen wrote his first volume of fairy tales, and Mozart composed *The Marriage of Figaro*. One early study of creativity found that individuals' most creative products were generated in their thirties and that 80 percent of the most important creative contributions were completed by age 50 (Lehman, 1960). More recently, researchers have found that creativity often peaks in the forties before declining (Simonton, 1996, 2019, 2021). However, any generalization about a link between age and creative accomplishments must be qualified by consideration of (1) the size of the decline and (2) differences across domains (Jones, Reedy, & Weinberg, 2014).

Even though a decline in creative contributions is often found in the fifties and later, the decline is often not great. And a study of artists from 53 to 75 years of age found no age differences in the artists' perceptions of their creativity (Reed, 2005). An impressive array of creative accomplishments have occurred in late adulthood (Tahir & Gruber, 2003). Benjamin

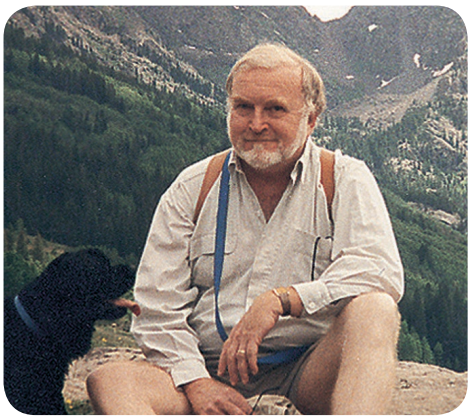
connecting development to life

Living a More Creative Life

Leading expert on creativity Mihaly Csikszentmihalyi (1996) interviewed 90 leading figures in art, business, government, education, and science to learn how creativity works. He discovered that creative people regularly engage in challenges that absorb them. Based on his interviews with some of the most creative people in the world, he concluded that the first step toward a more creative life is to cultivate your curiosity and interest. Here are his recommendations for doing this:

1. Try to be surprised by something every day. Maybe it is something you see, hear, or read about. Become absorbed in a lecture or a book. Be open to what the world is telling you. Life is a stream of experiences. Swim widely and deeply in it, and your life will be richer.
2. Try to surprise at least one person every day. In a lot of things you do, you have to be predictable and patterned. Do something different for a change. Ask a question you normally would not ask. Invite someone to go with you to a show or a museum you have never visited.
3. Write down each day what surprised you and how you surprised others. Most creative people keep a diary, notes, or lab records to ensure that their experience is not forgotten. Start with a specific task. Each evening, record the most surprising event that occurred that day and your most surprising action. After a few days, reread your notes and reflect on your experiences. After a few weeks, you might see a pattern emerging, one that suggests an area you can explore in greater depth.
4. When something sparks your interest, follow it. Usually when something captures your attention, it is short-lived—an idea, a song, a flower. Too often we are too busy to explore the idea, song, or flower further. Or we think these areas are none of our business because we are not experts about them. Yet the world is our business. We can't know which part of it is best suited to our interests until we make a serious effort to learn as much as we can about as many aspects of it as possible.
5. Wake up in the morning with a specific goal to look forward to. Creative people wake up eager to start the day. Why? Not necessarily because they are cheerful, enthusiastic types but because they know that there is something meaningful to accomplish each day, and they can't wait to get started.
6. Take charge of your schedule. Figure out which time of the day is your most creative time. Some of us are more creative late at night, others early in the morning. Carve out some time for yourself during the time when your creative energy is at its best.
7. Spend time in settings that stimulate your creativity. In Csikszentmihalyi's (1996) research, he gave people an electronic pager and beeped them randomly at different times of the day. When he asked them how they felt, they reported the highest levels of creativity when walking, driving, or swimming. For example, one person said, "I do my most creative thinking when I'm jogging." One experimental study compared the creative thinking skills of individuals after they had experienced one of four conditions: sitting inside, walking on a treadmill inside, walking outside, or being rolled outside in a wheelchair (Oppezzo & Schwartz, 2014). In this study, walking was more likely to produce the most creative thinking. Activities such as walking, jogging, and swimming are semiautomatic in that they take a certain amount of attention while leaving some time free to make connections among ideas. Another setting in which highly creative people report coming up with novel ideas is the half-asleep, half-awake state we are in when we are deeply relaxed or barely awake.



Leading creativity theorist Mihaly Csikszentmihalyi, in the setting where he gets his most creative ideas.
Dr. Mihaly Csikszentmihalyi

Can the strategies for stimulating creative thinking in children found earlier in this chapter also be used by adults? How do those strategies compare with those discussed here?

Franklin invented the bifocal lens when he was 78 years old; Wolfgang von Goethe completed *Faust* when he was in his eighties. After a distinguished career as a physicist, Henri Chevreul switched fields in his nineties to become a pioneer in gerontological research. He published his last research paper just a year prior to his death at the age of 103!

Furthermore, the age at which creativity typically declines varies with the domain involved. In philosophy and history, for example, older adults often show as much creativity as they did when they were in their thirties and forties. In contrast, in lyric poetry, abstract mathematics, and theoretical physics, the peak of creativity is often reached in the twenties or thirties.

Researchers have found that personality traits are linked to creativity (Hoffman & Feist, 2021). In one study, the personality trait of openness to experience predicted creativity in the arts, while intellect predicted creativity in the sciences (Kaufman & others, 2016).

Review *Connect* Reflect

LG4 Describe the characteristics of intellectual disability, giftedness, and creativity.

Review

- What is intellectual disability, and what are its causes?
- What makes people gifted?
- What makes people creative?

Connect

- Regarding children's critical-thinking skills and problem-solving strategies, what role, if any, might these play in determining whether children become creative thinkers?

Reflect *Your Own Personal Journey of Life*

- How many of the tips in the *Connecting Development to Life* interlude, "Living a More Creative Life," do you practice? In what ways might you benefit from these suggestions, in addition to becoming more creative?

Intelligence

1 The Concept of Intelligence

LG1 Explain the nature of intelligence.

What Is Intelligence?

- Intelligence consists of the ability to solve problems and to adapt and learn from experiences. A key aspect of intelligence focuses on its individual variations. Traditionally, intelligence has been measured by tests designed to compare people's performance on cognitive tasks.

Intelligence Tests

- Sir Francis Galton is considered the father of mental tests. Alfred Binet developed the first intelligence test and created the concept of mental age. William Stern developed the concept of IQ for use with the Binet test. Revisions of the Binet test are called the Stanford-Binet. The test scores on the Stanford-Binet approximate a normal distribution.
- The Wechsler scales, created by David Wechsler, are the other main intelligence assessment tool. These tests provide an overall IQ and yield several composite scores, allowing the examiner to identify strengths and weaknesses in different areas of intelligence.
- Test scores should be only one type of information used to evaluate an individual, not the only criterion. IQ scores can produce unfortunate stereotypes and expectations.

Theories of Multiple Intelligences

- Sternberg's triarchic theory states that there are three main types of intelligence: analytical, creative, and practical.
- Gardner identifies eight types of intelligence: verbal skills, mathematical skills, spatial skills, bodily-kinesthetic skills, musical skills, interpersonal skills, intrapersonal skills, and naturalist skills.
- Emotional intelligence is the ability to perceive and express emotion accurately and adaptively, to understand emotion and emotional knowledge, to use feelings to facilitate thought, and to manage emotions in oneself and others.
- The multiple intelligences approaches have broadened the definition of intelligence and motivated educators to develop programs that instruct students in different domains. Critics maintain that the multiple intelligences theories include factors that really aren't part of intelligence, such as musical skills and creativity. Critics also say that not enough research has been done to support the concept of multiple intelligences.

The Neuroscience of Intelligence

- Interest in discovering links between the brain and intelligence has been stimulated by advances in brain imaging. A moderate correlation has been found between brain size and intelligence.
- Some experts emphasize that the highest level of intelligence that involves reasoning is linked to the prefrontal cortex. However, other researchers recently have found a link between intelligence and a distributed neural network in the frontal and parietal lobes. The search for a connection between neural processing speed and intelligence has produced mixed results.

2 Controversies and Group Comparisons

LG2 Outline key controversies about differences in IQ scores.

The Influence of Heredity and Environment

- Genetic similarity might explain why identical twins show stronger correlations on intelligence tests than fraternal twins do.
- In recent decades there has been a considerable rise in intelligence test scores around the world—called the Flynn effect—and this supports the role of environment in intelligence.
- Researchers have found that the extent to which parents talk with their children in the first three years of life is correlated with the children's IQs and that being deprived of formal education lowers IQ scores. Ramey's research revealed the positive effects of educationally oriented child care on intelligence.

Group Comparisons and Issues

- Cultures vary in the way they define intelligence. Early intelligence tests favored non-Latinx White, middle-socioeconomic-status, urban individuals.
- Tests may be biased against certain groups that are not familiar with a standard form of English, with the content tested, or with the testing situation. Stereotype threat may produce ethnic/cultural bias that reduces intelligence test scores.
- Tests are likely to reflect the values and experience of the dominant culture. In the United States, the average score of African American children is below the average score of non-Latinx White children on standardized intelligence tests, but as African Americans have gained economic, social, and educational opportunities, the gap between these average scores has been decreasing.

3 The Development of Intelligence

LG3 Discuss the development of intelligence across the life span.

Tests of Infant Intelligence

- The Bayley scales are widely used to assess infant intelligence. The Fagan Test of Infant Intelligence, which assesses how effectively infants process information, is increasingly being used.

Stability and Change in Intelligence Through Adolescence

- Although intelligence is more stable across childhood and adolescence than are many other attributes, many children's and adolescents' scores on intelligence tests fluctuate considerably.

Intelligence in Adulthood

- Horn argued that crystallized intelligence continues to increase in middle adulthood, whereas fluid intelligence begins to decline. Schaie found that when assessed longitudinally, inductive reasoning is less likely to decline and more likely to improve than when assessed cross-sectionally in middle adulthood.
- The highest level of four intellectual abilities (vocabulary, verbal memory, inductive reasoning, and spatial orientation) occurs in middle adulthood.
- Baltes emphasizes a distinction between cognitive mechanics (the "hardware" of the mind, reflecting the neurophysiological architecture of the brain) and cognitive pragmatics (the culture-based "software" of the mind). Cognitive mechanics are more likely to decline in older adults than are cognitive pragmatics.
- Wisdom is expert knowledge about the practical aspects of life that permits excellent judgment about important matters. Baltes and his colleagues have found that high levels of wisdom are rare, factors other than age are critical for a high level of wisdom to develop, and personality-related factors are better predictors of wisdom than cognitive factors such as intelligence. Sternberg proposed the balance theory of wisdom, which especially emphasizes concern for the common good and doing the right thing.

4 The Extremes of Intelligence and Creativity

LG4 Describe the characteristics of intellectual disability, giftedness, and creativity.

Intellectual Disability

- Intellectual disability is a condition of limited mental ability in which the individual (1) has a low IQ, usually below 70; (2) has difficulty adapting to the demands of everyday life; and (3) has an onset of these characteristics by age 18.
- Most individuals with an intellectual disability have an IQ in the 55 to 70 range (mild intellectual disability). Intellectual disability can have an organic cause or a cultural/familial cause.

Giftedness

- People who are gifted have high intelligence (an IQ of 130 or higher) or some type of superior talent. Three characteristics of gifted children are precocity, marching to their own drummer, and a passion to achieve mastery in their domain.
- Giftedness is likely a consequence of both heredity and environment. A current concern is the education of children who are gifted.

Creativity

- Creativity is the ability to think about something in novel and unusual ways and come up with unique solutions to problems. Although most creative people are intelligent, individuals with high IQs are not necessarily creative. Creative people tend to be divergent thinkers, but traditional intelligence tests measure convergent thinking.
- Creativity has often been described as occurring in a five-step process: preparation, incubation, insight, evaluation, and elaboration.
- Characteristics of creative thinkers include flexibility and playful thinking, inner motivation, a willingness to take risks, and interest in objective evaluation.
- Creativity often peaks in the forties and then declines, but the decline may be slight and the peak age varies across domains. Csikszentmihalyi notes that cultivating curiosity and interest is the first step toward leading a more creative life.

preview

In this chapter, we will tell the remarkable story of language and how it develops. The questions we will explore include these: What is language? What is the course of language development across the life span? What does biology contribute to language? How do different experiences influence language?

1 What Is Language?

LG1 Define language and describe its rule systems.

Defining Language

Language's Rule Systems

Words not only affect us temporarily; they change us, they socialize us, and they unsocialize us.

—David Reisman
American Social Scientist, 20th Century

In 1799, a nude boy was observed running through the woods in France. The boy was captured when he was 11 years old. He was called the Wild Boy of Aveyron and was believed to have lived in the woods alone for six years (Lane, 1976). When found, he made no effort to communicate. He never learned to communicate effectively. A modern-day wild child named Genie was discovered in Los Angeles in 1970. Genie had been locked away in almost complete social isolation during her childhood. At age 13, Genie could not speak or stand erect. Sadly, despite intensive intervention, Genie never acquired more than a primitive form of language. Both cases—the Wild Boy of Aveyron and Genie—raise questions about the biological and environmental determinants of language, topics that we will examine later in the chapter. First, though, we need to define language.

Language allows us to communicate with others. *What are some important characteristics of language?*
FatCamera/Getty Images

language A form of communication, whether spoken, written, or signed, that is based on a system of symbols.

infinite generativity The ability to produce and comprehend an endless number of meaningful sentences using a finite set of words and rules.

phonology The sound system of a language—includes the sounds used and how they may be combined.

DEFINING LANGUAGE

Language is a form of communication—whether spoken, written, or signed—that is based on a system of symbols. Language consists of the words used by a community and the rules for varying and combining them.

Think how important language is in our everyday lives. We need language to speak with others, listen to others, read, and write. Our language enables us to describe past events in detail and to plan for the future. Language lets us pass down information from one generation to the next and create a rich cultural heritage. Language learning involves comprehending a sound system (or sign system for individuals who are deaf), the world of objects, actions, and events, and how units such as words and grammar connect sound and world (Bruhn de Garavito & Schwieter, 2021; Levine, Hirsh-Pasek, & Golinkoff, 2021).

All human languages have some common characteristics (Quam & Creel, 2021). These include infinite generativity and organizational rules. **Infinite generativity** is the ability to produce and comprehend an endless number of meaningful sentences using a finite set of words and rules. Rules describe the way language works. Let's explore what these rules involve.

LANGUAGE'S RULE SYSTEMS

When nineteenth-century American writer Ralph Waldo Emerson said, "The world was built in order and the atoms march in tune," he must have had language in mind. Language is highly ordered and organized (Lopez, 2020; Westbury, 2021). The organization involves five systems of rules: phonology, morphology, syntax, semantics, and pragmatics.

Phonology Every language is made up of basic sounds. **Phonology** is the sound system of the language, including the sounds that are used and how they may be combined (Bruhn de Garavito, 2021a; Vihman, 2020). For example, English has the initial consonant cluster *spr* as in *spring,* but no words begin with the cluster *rsp*.

Phonology provides a basis for constructing a large and expandable set of words out of two or three dozen phonemes (Warlaumont, 2021). A *phoneme* is the basic unit of sound in a language; it is the smallest unit of sound that affects meaning (Shea & O'Neill, 2021). For

example, in English the sound represented by the letter *p*, as in the words *pot* and *spot*, is a phoneme. The /p/ sound is slightly different in the two words, but this variation is not distinguished in English, and therefore the /p/ sound is a single phoneme. In some languages, such as Hindi, the variations of the /p/ sound represent separate phonemes.

Morphology

Morphology refers to the units of meaning involved in word formation. A *morpheme* is a minimal unit of meaning; it is a word or a part of a word that cannot be broken into smaller meaningful parts (Levine, Hirsh-Pasek, & Golinkoff, 2021). Every word in the English language is made up of one or more morphemes. Some words consist of a single morpheme (for example, *help*), whereas others are made up of more than one morpheme (for example, *helper* has two morphemes, *help* and *er*, with the morpheme *-er* meaning "one who"—in this case "one who helps"). Thus, not all morphemes are words by themselves—for example, *pre-*, *-tion*, and *-ing* are morphemes.

Just as the rules that govern phonology describe the sound sequences that can occur in a language, the rules of morphology describe the way meaningful units (morphemes) can be combined in words (Bruhn de Garavito, 2021b). Morphemes have many jobs in grammar, such as marking tense (for example, "she walks" versus "she walked") and number ("she walks" versus "they walk").

Syntax

Syntax involves the way words are combined to form acceptable phrases and sentences (Bruhn de Garavito, 2021c). If someone says to you, "Bob slugged Tom" or "Bob was slugged by Tom," you know who did the slugging and who was slugged in each case because you have a syntactic understanding of these sentence structures. You also understand that the sentence "You didn't stay, did you?" is a grammatical sentence but that "You didn't stay, didn't you?" is unacceptable and ambiguous.

If you learn another language, English syntax will not get you very far. For example, in English an adjective usually precedes a noun (as in *blue sky*), whereas in Spanish the adjective usually follows the noun (*cielo azul*). Despite the differences in their syntactic structures, however, syntactic systems in all of the world's languages have some common ground. For example, no language we know of permits sentences like the following one:

The mouse the cat the farmer chased killed ate the cheese.

It appears that language users cannot process subjects and objects arranged in too complex a fashion in a sentence.

Semantics

Semantics refers to the meaning of words and sentences. Every word has a set of semantic features, which are required attributes related to meaning (Ferreira & others, 2021). *Girl* and *woman*, for example, share many semantic features, but they differ semantically in regard to age.

Words have semantic restrictions on how they can be used in sentences (Polišenská & others, 2021). The sentence *The bicycle talked the boy into buying a candy bar* is syntactically correct but semantically incorrect. The sentence violates our semantic knowledge that bicycles don't talk.

Pragmatics

A final set of language rules involves **pragmatics,** the appropriate use of language in different contexts. Pragmatics covers a lot of territory (Taboada, 2021). When you take turns speaking in a discussion or use a question to convey a command ("Why is it so noisy in here? What is this, Grand Central Station?"), you are demonstrating knowledge of pragmatics. You also apply the pragmatics of English when you use polite language in appropriate situations (for example, when talking to your teacher) or tell stories that are interesting, jokes that are funny, and lies that are convincing. In each of these cases, you are demonstrating that you understand the rules of your culture for adjusting language to suit the context.

Pragmatic rules can be complex and differ from one culture to another (Nadasdi, 2021). Consider the pragmatics of saying "thank you." Even preschoolers' use of the phrase *thank you* varies with sex, socioeconomic status, and the age of the individual they are addressing. If you were to study the Japanese language, you would come face-to-face with countless pragmatic rules about how to say "thank you" to individuals of various social levels and with various relationships to you.

In this section, we have discussed five important rule systems involved in language. An overview of these rule systems is presented in Figure 1.

morphology Units of meaning involved in word formation.

syntax The ways words are combined to form acceptable phrases and sentences.

semantics The meanings of words and sentences.

pragmatics The appropriate use of language in different contexts.

Rule System	Description	Examples
Phonology	The sound system of a language. A phoneme is the smallest sound unit in a language.	The word *chat* has three phonemes or sounds: /ch/ /ă/ /t/. An example of a phonological rule in the English language is while the phoneme /r/ can follow the phonemes /t/ or /d/ in an English consonant cluster (such as *track* or *drab*), the phoneme /l/ cannot follow these letters.
Morphology	The system of meaningful units involved in word formation.	The smallest sound units that have a meaning are called morphemes, or meaning units. The word *girl* is one morpheme, or meaning unit; it cannot be broken down any further and still have meaning. When the suffix *s* is added, the word becomes *girls* and has two morphemes because the *s* changed the meaning of the word, indicating that there is more than one girl.
Syntax	The system that involves the way words are combined to form acceptable phrases and sentences.	Word order is very important in determining meaning in the English language. For example, the sentence "Sebastian pushed the bike" has a different meaning from "The bike pushed Sebastian."
Semantics	The system that involves the meaning of words and sentences.	Semantics involves knowing the meaning of individual words—that is, vocabulary. For example, semantics includes knowing the meaning of such words as *orange*, *transportation*, and *intelligent*.
Pragmatics	The system of using appropriate conversation and knowledge of how to effectively use language in context.	An example is using polite language in appropriate situations, such as being mannerly when talking with one's teacher. Taking turns in a conversation involves pragmatics.

FIGURE **1**

THE RULE SYSTEMS OF LANGUAGE.

Review *Connect* Reflect

LG1 Define language and describe its rule systems.

Review

- What is language?

Reflect *Your Own Personal Journey of Life*

- How good are your family members and friends at the pragmatics of language? Describe a situation in which an individual showed pragmatic skills and another in which a person did not.

2 How Language Develops

LG2 Describe how language develops through the life span.

Infancy | Early Childhood | Middle and Late Childhood | Adolescence | Adulthood and Aging

In the thirteenth century, Emperor Frederick II of Germany had a cruel idea. He wanted to know what language children would speak if no one talked to them. He selected several newborns and threatened their caregivers with death if they ever talked to the infants. Frederick never found out what language the children spoke because they all died. As we move forward in the twenty-first century, we are still curious about infants' development of language, although our experiments and observations are, to say the least, far more humane than the evil Frederick's.

INFANCY

Whatever language they learn, infants all over the world follow a similar path in language development. What are some key milestones in this development?

Babbling and Other Vocalizations Long before infants speak recognizable words, they produce a number of vocalizations (Choi & others, 2020; Meyer & Hunnius, 2021). The functions of these early vocalizations are to practice making sounds, to communicate, and to attract attention (Lee & others, 2018). Babies' sounds go through the following sequence during the first year:

- *Crying*. Babies cry even at birth. Crying can signal distress, but different types of cries signal different things.
- *Cooing*. Babies first coo at about 2 to 4 months. These gurgling sounds that are made in the back of the throat usually express pleasure during interaction with the caregiver.
- *Babbling*. In the middle of the first year, babies babble—that is, they produce strings of consonant-vowel combinations, such as *ba, ba, ba, ba* (Lang & others, 2021).

In one study, the age at which infants began babbling predicted when they would say their first words (McGillion & others, 2017a). Also, in another study, a lack of babbling in infants was linked to a risk of having future speech and language problems (Lohmander & others, 2017). And in recent research, infants' babbling has been shown to influence the behavior of their caregivers, creating social interaction that facilitates infants' language development (Casillas, Brown, & Levinson, 2020).

Gestures Infants start using gestures, such as showing and pointing, at about 8 to 12 months of age. They may wave bye-bye, nod to mean "yes," show an empty cup to ask for more milk, and point to a dog to draw attention to it. Some early gestures are symbolic, as when an infant smacks her lips to indicate food or drink. Pointing is considered by language experts to be an important index of the social aspects of language, and it follows a specific developmental sequence: from pointing without checking on adult gaze to pointing while looking back and forth between an object and the adult (Begus & Southgate, 2012).

Lack of pointing is a significant indicator of problems in the infant's communication system (Fenlon & others, 2019). Pointing is a key aspect of the development of joint attention and an important index of the social aspects of language (Goldin-Meadow, 2020). Failure to engage in pointing also characterizes many autistic children. In a recent study, infants at high risk for autism spectrum disorder used fewer gestures than their counterparts who were at low risk for autism spectrum disorder (Choi & others, 2021). The ability to use the pointing gesture effectively improves in the second year of life as advances in other aspects of language communication occur.

One study found that parents in families with high socioeconomic status (SES) were more likely to use gestures when communicating with their 14-month-old infants (Rowe & Goldin-Meadow, 2009). Further, the infants' use of gestures at 14 months of age in high-SES families was linked to a larger vocabulary at 54 months of age. And in a recent study, parents who gestured more with their 12-month-old infants had children with a better vocabulary at 36 months (Choi & others, 2021).

Why might gestures such as pointing promote further language development? Infants' gestures advance their language development since caregivers often talk to them about what they are pointing to. Also, babies' first words often are for things they have previously pointed to.

Long before infants speak recognizable words, they communicate by producing a number of vocalizations and gestures. *At approximately what ages do infants begin to produce different types of vocalizations and gestures?*
Don Hammond/Design Pics

Recognizing Language Sounds Long before they begin to learn words, infants can make fine distinctions among the sounds of spoken language. In Patricia Kuhl's (2000, 2011, 2015, 2021) research, phonemes from languages all over the world are piped through a speaker for infants to hear (see Figure 2). A box with a toy bear in it is placed where the infant can see it. A string of identical syllables is played, and then the syllables are changed (for example, *ba ba ba ba*, and then *pa pa pa pa*). If the infant turns its head when the syllables change, the box lights up and the bear dances and drums, rewarding the infant for noticing the change.

Kuhl's research (2007, 2009, 2011, 2015, 2021) has demonstrated that from birth to about 6 months of age, infants are "citizens of the world": They recognize when sounds change most of the time, no matter what language the syllables come from. But over the next six months, infants get even better at perceiving the changes in sounds from their "own" language, the one their parents speak, and they gradually lose the ability to recognize differences that are not important in their own language. Kuhl (2015) found that the period when a baby's brain is most open to learning the sounds of a native language begins at six months for vowels and at nine months for consonants.

FIGURE 2

FROM UNIVERSAL LINGUIST TO LANGUAGE-SPECIFIC LISTENER. In Patricia Kuhl's research laboratory, babies listen to tape-recorded voices that repeat syllables. When the sounds of the syllables change, the babies quickly learn to look at the bear. Using this technique, Kuhl has demonstrated that babies are universal linguists until about 6 months of age, but in the next six months become language-specific listeners. *Does Kuhl's research give support to the view that either "nature" or "nurture" is the source of language acquisition?*

Courtesy of Dr. Patricia Kuhl, Institute for Learning and Brain Sciences, University of Washington

Also, in the second half of the first year, infants begin to segment the continuous stream of speech they encounter into words (Ota & Skarabela, 2018). Initially, they likely rely on statistical information such as the co-occurrence patterns of phonemes and syllables, which allows them to extract potential word forms (Arnon, 2019). For example, discovering that the sequence *br* occurs more often at the beginning of words while *nt* is more common at the end of words helps infants detect word boundaries. And as infants extract an increasing number of potential word forms from the speech stream they hear, they begin to associate these with concrete, perceptually available objects in their world (Saffran & Kirkham, 2018). For example, infants might detect that the spoken word "monkey" has a reliable statistical regularity of occurring in the visual presence of an observed monkey but not in the presence of other animals, such as bears (Pace & others, 2016). Thus, statistical learning involves extracting information from the world to learn about the environment (Lany & Shoaib, 2020).

Richard Aslin (2017) recently emphasized that statistical learning—which involves no instruction, reinforcement, or feedback—is a powerful learning mechanism in infant development. In statistical learning, infants soak up statistical regularities in the world merely through exposure to them (Jayaraman & Smith, 2021). Aslin (2020) concludes that in addition to word segmentation from fluent speech, statistical learning has been documented in many other domains, such as musical tones, phonetic categories, sequences of visual shapes, sequences of motor responses, and combinations of object parts in complex visual scenes.

What characterizes the infant's early word learning?

Africa Studio/Shutterstock

First Words Infants understand words before they can produce or speak them (Levine, Hirsh-Pasek, & Golinkoff, 2021). Between about 5 and 12 months of age, infants often indicate their first understanding of words. For many infants, the first word they understand is their own name (Bortfield & others, 2005). The infant's first spoken word is a milestone eagerly anticipated by every parent. This event usually occurs between 10 and 15 months of age and at an average age of about 13 months. However, long before babies say their first words, they have been communicating with their parents, often by gesturing and using their own special sounds. The appearance of first words is a continuation of this communication process (Blinkoff & others, 2020).

A child's first words include those that name important people (*dada*), familiar animals (*kitty*), vehicles (*car*), toys (*ball*), food (*milk*), body parts (*eye*), clothes (*hat*), household items (*clock*), and greeting terms (*bye*). Children often express various intentions with their single words, so that *cookie* might mean "That's a cookie" or "I want a cookie." Nouns are easier to learn because the majority of words in this class are more perceptually accessible than other types of words (Parish-Morris, Golinkoff, & Hirsh-Pasek, 2013). Think how the noun "car" is so much more concrete and imaginable than the verb "goes," making the word "car" much easier to acquire than the word "goes."

The first words of infants can vary across languages. The first words of English-speaking and Romance-language-speaking infants usually are nouns. However, because of the structure of the Korean language, the early words of Korean infants may be verbs (Choi & Gopnik, 1995). Indeed, the language of Korean children is often described as verb-friendly and the language of English children as noun-friendly (Waxman & others, 2013).

On average, infants understand about 50 words by 13 months of age, but they can't say that many words until about 18 months (Menyuk, Liebergott, & Schultz, 1995). Thus, in infancy *receptive vocabulary* (words the child understands) considerably exceeds *spoken vocabulary* (words the child uses).

The infant's spoken vocabulary rapidly increases once the first word is spoken (Levine, Hirsh-Pasek, & Golinkoff, 2021). The average 18-month-old can speak about 50 words, but the average 2-year-old can speak about 200 words. This rapid increase in vocabulary that begins at approximately 18 months is called the vocabulary spurt (Bloom, Lifter, & Broughton, 1985). The spurt actually involves an increase in the rate at which words are learned. That is, early on, a few words are learned every few days, later a few words are learned each day, and eventually many words are learned each day.

We have described the average number of words infants and toddlers can speak. However, there is variability in the number of words infants and children can speak, with some speaking far fewer words and others far more than the averages. Not only is there variation in the number of words they can speak and when the timing of the vocabulary spurt occurs, but also in the extent to which they are "spurty." That is, some children learn new words at an accelerating pace, while others do not.

Does early vocabulary development predict later language development? Research studies indicate that it does (Rajan & others, 2019). One study found that infant vocabulary development at 16 to 24 months of age was linked to vocabulary, phonological awareness, reading accuracy, and reading comprehension five years later (Duff & others, 2015).

Like the timing of a child's first word, the timing of the vocabulary spurt varies. Figure 3 shows the range for these two language milestones in 14 children (Bloom, 1998). On average, these children said their first word at 13 months and had a vocabulary spurt at 19 months. However, the ages for the first word of individual children varied from 10 to 17 months and for their vocabulary spurt from 13 to 25 months.

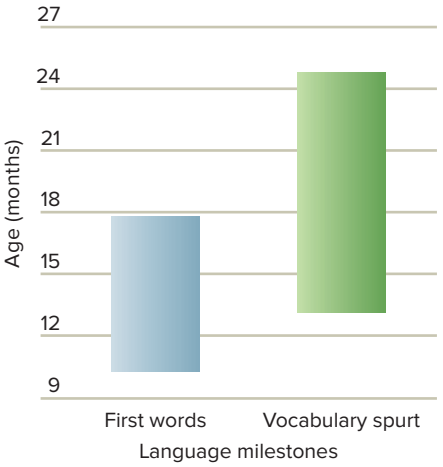

FIGURE **3**

VARIATION IN LANGUAGE MILESTONES. *What are some possible explanations for variations in the timing of these milestones?*

Cross-linguistic differences occur in word learning (Waxman & others, 2013). Children learning Mandarin Chinese, Korean, and Japanese acquire more verbs earlier in their development than do children learning English. This cross-linguistic difference reflects the greater use of verbs in the language input to children in these Asian languages.

Children sometimes overextend or underextend the meanings of the words they use (Woodward & Markman, 1998). *Overextension* is the tendency to apply a word to objects that are inappropriate for the word's meaning by going beyond the set of referents an adult would use. For example, children at first may say "*dada*" not only for "father" but also for other men, strangers, or boys. With time, overextensions decrease and eventually disappear. *Underextension* is the tendency to apply a word too narrowly; it occurs when children fail to use a word to name a relevant event or object. For example, a child might use the word *boy* to describe a 5-year-old neighbor but not apply the word to a male infant or to a 9-year-old male.

Two-Word Utterances By the time children are 18 to 24 months of age, they usually vocalize two-word utterances (Tomasello, 2011). To convey meaning with just two words, the child relies heavily on gesture, tone, and context. Children can communicate a wealth of meaning with a two-word utterance, as illustrated below (Slobin, 1972):

- Identification: "See doggie."
- Location: "Book there."
- Repetition: "More milk."
- Nonexistence: "All gone."
- Possession: "My candy."
- Attribution: "Big car."
- Agent-action: "Mama walk."
- Question: "Where ball?"

These examples are from children whose first language is English, German, Russian, Finnish, Turkish, or Samoan.

Notice that the two-word utterances omit many parts of speech and are remarkably succinct. In fact, in every language, a child's first combinations of words have this economical quality; they are telegraphic. **Telegraphic speech** is the use of short and precise words without grammatical markers such as articles, auxiliary verbs, and other connectives. Telegraphic speech is not limited to two words. "Mommy give ice cream" and "Mommy give Tommy ice cream" also are examples of telegraphic speech.

Around the world, most young children learn to speak in two-word utterances, in most cases at about 18 to 24 months of age. *What implications does this have for the biological basis of language?*

Sharla Peltier, Speech Therapist

A speech therapist is a health professional who works with individuals who have a communication disorder. Sharla Peltier, a speech therapist in Manitoulin, Ontario, Canada, works with Native American children in the First Nations schools. She conducts screenings for speech/language and hearing problems and assesses infants as young as 6 months of age as well as school-aged children. She works closely with community health nurses to identify hearing problems.

Diagnosing problems is only about half of what Peltier does in her work. She especially enjoys treating speech/language and hearing problems. She conducts parent training sessions to help parents understand and help with their children's language problem. As part of this training, she guides parents in communicating more effectively with their children.

For more information about what speech therapists do, see the Careers in Life-Span Development appendix.

Speech therapist Sharla Peltier helps a young child improve her language and communication skills.

Typical Age	Language Milestones
Birth	Crying
2 to 4 months	Cooing begins
5 months	Understands first word
6 months	Babbling begins
7 to 11 months	Change from universal linguist to language-specific listener
8 to 12 months	Uses gestures, such as showing and pointing Comprehension of words appears
13 months	First word spoken
18 months	Vocabulary spurt starts
18 to 24 months	Uses two-word utterances Rapid expansion of understanding of words

FIGURE **4**

SOME LANGUAGE MILESTONES IN INFANCY. Despite great variations in the language input received by infants, around the world they follow a similar path in learning to speak.

We have discussed a number of language milestones in infancy. Figure 4 summarizes the ages at which infants typically reach these milestones.

EARLY CHILDHOOD

Toddlers move rather quickly from producing two-word utterances to creating three-, four-, and five-word combinations. Between 2 and 3 years of age, they begin the transition from saying simple sentences that express a single proposition to saying complex sentences.

As young children learn the special features of their own language, there are extensive regularities in how they acquire that specific language (Bruhn de Garavito & Schwieter, 2021; Schwieter, 2021). For example, all children learn the prepositions *on* and *in* before other prepositions.

However, some children encounter obstacles to language development, including speech and hearing problems. To read about an individual who works with children who have speech/language problems, see the *Connecting with Careers* profile.

Understanding Phonology and Morphology During the preschool years, most children gradually become more sensitive to the sounds of spoken words and become increasingly capable of producing all the sounds of their language (Shea & O'Neill, 2021). By the time children are 3 years of age, they can produce all the vowel sounds and most of the consonant sounds (Stoel-Gammon & Sosa, 2010). They recognize the sounds in word combinations such as "Merry go round" before they can produce them.

By the time children move beyond two-word utterances, they demonstrate a knowledge of morphology rules (Bruhn de Garavito, 2021b). Children begin using the plural and possessive forms of nouns (such as *dogs* and *dog's*). They put appropriate endings on verbs (such as *-s* when the subject is third-person singular and *-ed* for the past tense). They use prepositions (such as *in* and *on*), articles (such as *a* and *the*), and various forms of the verb *to be* (such as "I was going to the store"). Some of the best evidence for changes in children's use of morphological rules occurs in their overgeneralization of the rules, as when a preschool child says "foots" instead of "feet," or "goed" instead of "went."

In a classic experiment that was designed to study children's knowledge of morphological rules, such as how to make a plural, Jean Berko (1958) presented preschool children and

first-grade children with cards such as the one shown in Figure 5. Children were asked to look at the card while the experimenter read aloud the words on the card. Then the children were asked to supply the missing word. This might sound easy, but Berko was interested in the children's ability to apply the appropriate morphological rule—in this case to say "wugs" with the *z* sound that indicates the plural.

What makes Berko's study impressive is that most of the words were made up for the experiment. Thus, the children could not base their responses on remembering past instances of hearing the words. That they could make the plurals or past tenses of words they had never heard before was proof that they knew the morphological rules.

Changes in Syntax and Semantics Preschool children also learn and apply rules of syntax (Bruhn de Garavito, 2021c). They show a growing mastery of complex rules for how words should be ordered.

Consider *wh-* questions, such as "Where is Daddy going?" or "What is that boy doing?" To ask these questions properly, the child must know two important differences between *wh-* questions and affirmative statements (for instance, "Mommy is going to work" and "That boy is waiting for the school bus"). First, a *wh-* word must be added at the beginning of the sentence. Second, the auxiliary verb must be inverted—that is, exchanged with the subject of the sentence. Young children learn quite early where to put the *wh-* word, but they take much longer to learn the auxiliary-inversion rule. Thus, preschool children might ask, "Where Daddy is going?" and "What that girl is doing?"

Gains in semantics also characterize early childhood. Vocabulary development is dramatic (Vukelich & others, 2020). Some experts have concluded that between 18 months and 6 years of age, young children learn words at the rate of about one new word every waking hour (Gelman & Kalish, 2006)! By the time they enter first grade, it is estimated that children know about 14,000 words (Clark, 1993). However, there are individual variations in children's vocabulary, and children who enter elementary school with a small vocabulary are at risk for developing reading problems (Berninger, 2006).

Why can children learn so many new words so quickly? One possibility is **fast mapping,** which involves children's ability to make an initial connection between a word and its referent after only limited exposure to the word (Weatherhead & others, 2021). Researchers have found that exposure to words on multiple occasions over several days results in more successful word learning than the same number of exposures in a single day (Childers & Tomasello, 2002). Also, fast mapping allows children to learn word meanings in a deeper sense, such as understanding where the word can be used and its nuances of meaning. In a recent study, fast mapping was documented as early as 24 months of age in remembering novel object names after a single learning event (Remon & others, 2020).

What are some important aspects of word learning? Following are six key principles in young children's vocabulary development (Harris, Golinkoff, & Hirsh-Pasek, 2011):

1. *Children learn the words they hear most often.* They learn the words that they encounter when interacting with parents, teachers, siblings, or peers, as well as when they are reading books (or being read to) and watching videos. They especially benefit from encountering words that they do not know.
2. *Children learn words for things and events that interest them.* Parents and teachers can direct young children to experience words in contexts that interest the children; playful peer interactions are especially helpful in this regard.
3. *Children learn words best in responsive and interactive contexts rather than passive contexts.* Children who experience turn-taking opportunities, joint focusing experiences, and positive, sensitive socializing contexts with adults encounter the scaffolding necessary for optimal word learning. They learn words less effectively when they are passive learners.
4. *Children learn words best in contexts that are meaningful.* Young children learn new words more effectively when new words are encountered in integrated contexts rather than as isolated facts.
5. *Children learn words best when they access clear information about word meaning.* Children whose parents and teachers are sensitive to words the children might not understand and provide support and elaboration with hints about word meaning learn words better than those whose parents and teachers quickly state a new word without monitoring whether children understand its meaning.

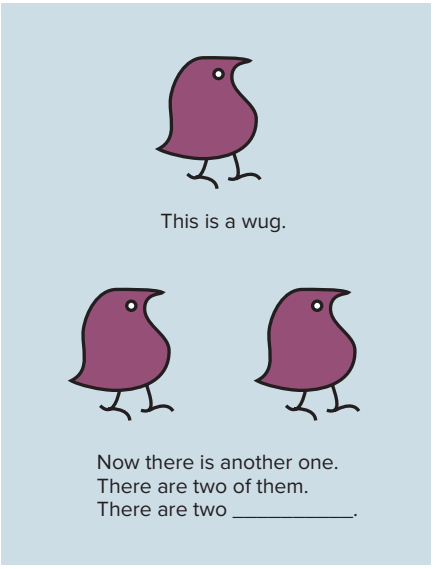

FIGURE **5**

STIMULI IN BERKO'S CLASSIC STUDY OF CHILDREN'S UNDERSTANDING OF MORPHOLOGICAL RULES. In Jean Berko's study, young children were presented with cards such as this one with a "wug" on it. Then the children were asked to supply the missing word and say it correctly.
Jean Berko (Gleason). "The Child's Learning of English Morphology." Word, 1958. By permission of the author.

fast mapping A process that helps to explain how young children learn the connection between a word and its referent so quickly.

6. *Children learn words best when grammar and vocabulary are considered.* Children who experience a large number of words used in a wide variety of sentences develop a richer vocabulary and better understanding of grammar. Vocabulary learning and grammatical development are connected.

How might a family's socioeconomic status influence parent-child communication and vocabulary growth in children?

Betty Hart and Todd Risley (1995) observed the language environments of children whose parents were professionals and children whose parents were on welfare. Compared with the professional parents, the parents on welfare talked much less to their young children, talked less about past events, and provided less elaboration. As indicated in Figure 6, the children of the professional parents had a much larger vocabulary at 36 months of age than the children whose parents were on welfare. Another study found that at 18 to 24 months of age, infants in low-SES families already had a smaller vocabulary and less efficient language processing than their infant counterparts in middle-SES families (Fernald, Marchman, & Weisleder, 2013). Further, in a recent study of English-speaking preschool children, those from lower-income families had less advanced language-processing skills than their counterparts from middle-income families, as well as syntax deficiencies and smaller vocabularies (Levine & others, 2020). And in another recent study, children living in extreme poverty had much lower levels of vocabulary and reading comprehension (Lervag & others, 2019).

Other research has linked how much mothers speak to their infants and the infants' vocabularies. For example, in one study by Janellen Huttenlocher and her colleagues (1991), infants whose mothers spoke more often to them had markedly larger vocabularies. By the second birthday, vocabulary differences were substantial. However, a study of 1- to 3-year-old children living in low-income families found that the sheer amount of maternal talk was not the best predictor of a child's vocabulary growth (Pan & others, 2005). Rather, it was maternal language and literacy skills that were positively related to the children's vocabulary development. For example, when mothers used a more diverse vocabulary when talking with their children, their children's vocabulary benefited, but their children's vocabulary was not related to the total amount of time mothers spent talking to their children.

Children in low-income families are more likely to have less-educated parents, receive inadequate nutrition, live in low-income communities, and attend substandard schools than children in middle- and high-income families (Mayo & Wadsworth, 2020). Living in a low-income family should not be used as the sole identifier in predicting whether children will have difficulties in language development, such as a smaller vocabulary and reading problems. For example, in a recent study of low-income families, 15-month-olds whose mothers had a college education had much better language skills than their low-income counterparts whose mothers did not have a college degree, and this gap continued through 3 years of age (Justice & others, 2020).

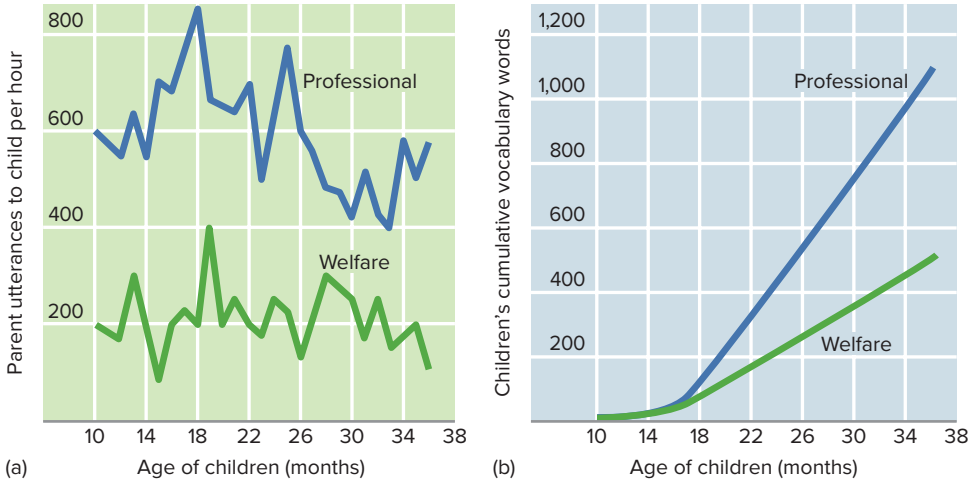

FIGURE 6

LANGUAGE INPUT IN PROFESSIONAL AND WELFARE FAMILIES AND YOUNG CHILDREN'S VOCABULARY DEVELOPMENT. (*a*) In this study (Hart & Risley, 1995), parents from professional families talked with their young children more than parents from welfare families. (*b*) All of the children learned to talk, but children from professional families developed vocabularies that were twice as large as the vocabularies of children from welfare families. Thus, by the time children go to preschool, they already have experienced considerable differences in language input in their families and developed different levels of vocabulary that are linked to their socioeconomic context.

If children growing up in low-income families experience effective interaction, instruction, and support, they can develop effective language skills (Florit & others, 2021; Masek & others, 2021). For example, in a recent meta-analysis (use of statistical techniques to combine the results of research studies) sensitive responsiveness of parents in low-SES families was linked to greater improvement in young children's language development than was the case in middle- and upper-SES families in which the parents showed lower levels of sensitive responsiveness (Madigan & others, 2019).

What types of challenges might deaf or hard of hearing children encounter in communicating with hearing parents, and what might be the long-term effects of these communication challenges? To learn about this topic, see the *Connecting with Research* interlude.

What Are the Effects of Communication Difficulties Between Hearing Parents and Deaf Children?

Courtesy Dr. Poorna Kushalnagar

Poorna Kushalnagar
Key Points:

- deaf and hard of hearing people
- adverse child communication experiences
- parent-child relationship

Dr. Poorna Kushalnagar is a deaf woman who understands firsthand the communication challenges faced by those who are deaf or hard of hearing (DHH) (Deaf Women United, 2019). She is also a professor at Gallaudet University and the director of the Deaf Health Communication and Quality of Life Research Lab. One of the many studies she has conducted explored the self-reported experiences of DHH young adults, specifically recent college graduates, regarding a potential association between the quality of communication with their parents as they were growing up and the current presence or absence of depressive symptoms (Kushalnagar & others, 2017).

In comparison with hearing children communicating with a parent, DHH children have the added challenge of accurately and completely gathering the literal words and any related facial expressions or gestures used before determining what those words or gestures mean. Once satisfied that they have accurately received the message, DHH children then process the information, attempt their response, and then try to assess whether the literal communication was accurately received by the parent. In some cases, a DHH child may struggle to communicate with a parent who is not proficient at sign language or hard to follow using lip reading. This may lead the DHH child to routinely ask the parent to slow down or repeat the message. While some parents have the patience to take as long as needed for accurate communication, others may decide the message is not worth the effort or wait to try again later. Such continual frustrations may lead both the DHH child and the parent to avoid or reduce attempts at communication.

What are some of the challenges that children who are deaf or hard of hearing face?
insta_photos/Shutterstock

While studies have shown that DHH children who continually deal with communication challenges are more likely to experience depression than children who do not face these challenges, Dr. Kushalnagar theorized that depression rates might differ in a college-educated sample of DHH young adults. To explore this question, 143 DHH college graduates (average age: 22 years) were studied. The sample was diverse in terms of gender (65 males, 78 females), ethnicity (78 identified as not Caucasian), hearing level (21 reported mild to moderate hearing impairment, 79 reported severe to profound deafness), and preferred language (58 percent preferred American Sign Language, 42 percent preferred English).

The participants rated their communication history with their parents by responding to questions such as the following:

> When you were a child, how well did you understand what your mother said?
> 1 = Most or all of what she said
> 2 = Some of what she said
> 3 = Little or none of what she said

Participants were also given a well-known measure of depression called the Beck Depression Inventory.

Data analysis indicated that 24 percent of the participants met the criteria for depression, which is lower than the estimated rate of 44 percent among the overall DHH population. This finding suggests that the DHH college graduates differ from the general DHH adult population. Another interesting finding is that there were no gender differences in rates of depression. In the general population women often experience higher rates of depression than men. Possibly DHH men may struggle with societal expectations more than men in the general population, thus leading to more depressive symptoms. For example, traditional gender roles require men to be independent and strong; thus, a DHH man who requires assistance or repetition in communication might not conform to societal expectations.

Regarding the primary research question, participants with a history of communication difficulties with parents experienced higher rates of depression as young adults than those who reported having understood most or all of what their parents said. More specifically, DHH women were most affected by communication difficulties with their mothers, while DHH men were most affected by communication difficulties with their fathers. In the final analysis, those who reported being able to understand only some or none of what their same-gender parent said were eight times more likely to be depressed than those who reported understanding most or all of what their same-gender parent said.

What might be the effects of single-parenting or a divorce on a young DHH child?

What characterizes advances in pragmatics during early childhood?
Hill Street Studios/age fotostock

Advances in Pragmatics Changes in pragmatics also characterize young children's language development (Taboada, 2021). A 6-year-old is simply a much better conversationalist than a 2-year-old is. What are some of the improvements in pragmatics during the preschool years?

Young children begin to engage in extended discourse. For example, they learn culturally specific rules of conversation and politeness and become sensitive to the need to adapt their speech in different settings. Their developing linguistic skills and increasing ability to take the perspective of others contribute to their generation of more competent narratives.

As children get older, they become increasingly able to talk about things that are not here (Grandma's house, for example) and not now (what happened to them yesterday or might happen tomorrow, for example). A preschool child can tell you what she wants for lunch tomorrow, something that would not have been possible at the two-word stage of language development.

Around 4 to 5 years of age, children learn to change their speech style to suit the situation. For example, even 4-year-old children speak to a 2-year-old differently from the way they speak to a same-aged peer; they use shorter sentences with the 2-year-old. They also speak to an adult differently from the way they speak to a same-aged peer, using more polite and formal language with the adult (Shatz & Gelman, 1973).

Early Literacy Concern about the proficiency levels of U.S. children in reading and writing has led to a careful examination of preschool and kindergarten children's experiences, with the hope that a positive orientation toward reading and writing can be developed early in life (Tompkins & Rodgers, 2020). What should a literacy program for preschool children be like? The most obvious necessity is knowing a language. Children will not be able to comprehend the text they read if they don't understand the words and sentence structures. Instruction should be built on what children already know about oral language, reading, and writing (Vukelich & others, 2020). Parents and teachers need to provide a supportive environment to help children develop literacy skills (Walker & others, 2020). A recent study found that teacher-perceived conflict predicted lower interest and reduced levels of pre-academic literacy skill acquisition in young children (Pakarinen & others, 2021).

So far, our discussion of early literacy has focused on U.S. children. Researchers have found that the extent to which phonological awareness is linked to learning to read effectively varies across different languages to some degree (McBride-Chang, 2004). For example, one study of second-grade students from Beijing, Hong Kong, Korea, and the United States revealed that phonological awareness may be more important for early reading development in English and Korean than in Chinese (McBride-Chang & others, 2005). Further, rates of dyslexia (severe reading disability) differ across countries and are linked with the spelling and phonetic rules that characterize the language (McCardle & others, 2011). English is one of the more difficult languages because of its irregular spellings and pronunciations. In countries where English is spoken, the rate of dyslexia is higher than in countries where the alphabet script is more phonetically pronounced.

What are some strategies for increasing young children's literacy?
JGI/Jamie Grill/Blend Images/Getty Images

Books can be valuable in enhancing children's communication skills (Morrow, 2020). What are some strategies for using books effectively with preschool children? Ellen Galinsky (2010) offered these recommendations:

- *Use books to initiate conversation with young children.* Ask them to put themselves in the places of the characters in the book and to imagine what the characters might be thinking or feeling.
- *Use* what *and* why *questions.* Ask young children to think about what is going to happen next in a story and then to see if it occurs.
- *Encourage children to ask questions about stories.*
- *Choose some books that play with language.* Creative books on the alphabet, including those with rhymes, often interest young children.

MIDDLE AND LATE CHILDHOOD

Upon entering school, children gain new skills that include increasing use of language to talk about things that are not physically present, knowledge of what a word is, and the capacity to recognize and talk about sounds. They learn the *alphabetic principle*—the fact that the letters of the alphabet represent sounds of the language. As children develop during middle and late childhood, changes in their vocabulary and grammar continue to take place.

Vocabulary, Grammar, and Metalinguistic Awareness During middle and late childhood, children begin to organize their mental vocabulary in new ways. When asked to say the first word that comes to mind when they hear a word, young children typically provide a word that often follows the word in a sentence. For example, when asked to respond to "dog," the young child may say "barks." In response to the word "eat," they may say "lunch." At about 7 years of age, children begin to respond with a word that is the same part of speech as the stimulus word. For example, a child may now respond to the word "dog" with "cat" or "horse." To "eat," they now might say "drink." This type of reply is evidence that children have begun to categorize their vocabulary by parts of speech .

The process of categorizing becomes easier as children increase their vocabulary. Children's vocabulary increases from an average of about 14,000 words at 6 years of age to an average of about 40,000 words by 11 years of age. Children make similar advances in grammar (Bruhn de Garavito, 2021c). During the elementary school years, children's improvement in logical reasoning and analytical skills helps them understand such constructions as the appropriate use of comparatives (*shorter, deeper*) and subjunctives ("If you were president . . ."). During the elementary school years, children become increasingly able to understand and use complex grammar, such as the following sentence: *The boy who kissed his mother wore a hat*. They also learn to use language in a more connected way, producing connected discourse.

These advances in vocabulary and grammar during the elementary school years are accompanied by the development of **metalinguistic awareness,** which is knowledge about language, such as knowing what a preposition is or being able to discuss the sounds of a language (Dong & others, 2020). Metalinguistic awareness allows children "to think about their language, understand what words are, and even define them" (Berko Gleason, 2009, p. 4). In one study, metalinguistic instruction improved the spelling and reading skills of children attending kindergarten (Schiff, Nuri Ben-Shushan, & Ben-Artzi, 2017). Metalinguistic awareness improves considerably during the elementary school years as defining words becomes a regular part of classroom discourse and children increase their knowledge of syntax while studying and talking about the components of sentences, such as nouns and verbs (Crain, 2012). And reading also expands metalinguistic awareness as children try to comprehend written text.

Children also make progress in understanding how to use language in culturally appropriate ways—pragmatics (Nadasdi, 2021). By the time they enter adolescence, most children know the rules for using language in everyday contexts—that is, what is appropriate to say and what is inappropriate to say in different situations.

Reading Before learning to read, children learn to use language to talk about things that are not present; they learn what a word is; and they learn how to recognize sounds and talk about them. If they develop a large vocabulary, their path to reading is smoother. Children who begin elementary school with a small vocabulary are at risk of falling behind their peers in learning to read. Vocabulary development plays an important role in reading comprehension (Gunning, 2020).

How did you learn to read? Debate about how children should be taught to read focuses on the whole-language approach versus the phonics approach (Dewitz & others, 2020).

The **whole-language approach** stresses that reading instruction should parallel children's natural language learning. In some whole-language classes, beginning readers are taught to recognize whole words or even entire sentences and to use the context of what they are reading to guess at the meaning of words. Reading materials that support the whole-language approach are whole and meaningful—that is, children are given material in its complete form, such as stories and poems, so that they learn to understand language's communicative function. Reading is connected with listening and writing skills. Although there are variations in whole-language programs, most share the premise that reading should be integrated with other skills and subjects, such as science and social studies, and that it should focus on real-world material. Thus, a class might read newspapers, magazines, or books and then write about and discuss what they have read.

metalinguistic awareness Knowledge about language.

whole-language approach A teaching approach built on the idea that reading instruction should parallel children's natural language learning and that reading materials should be whole and meaningful.

This teacher is helping a student sound out words. Researchers have found that phonics instruction is a key aspect of teaching students to read, especially beginning readers and students with weak reading skills.
Mordolff/Getty Images

In contrast, the **phonics approach** emphasizes that reading instruction should teach basic rules for translating written symbols into sounds. Early phonics-centered reading instruction should involve simplified materials. Only after children have learned correspondence rules that relate spoken phonemes to the alphabet letters that are used to represent them should they be given complex reading materials such as books and poems (Bear & others, 2020).

Which approach is better? Research suggests that children can benefit from both approaches, but instruction in phonics needs to be emphasized (Tompkins & Rodgers, 2020). An increasing number of experts in the field of reading now conclude that direct instruction in phonics is a key aspect of learning to read (Bear & others, 2020).

Beyond the phonics/whole-language issue in learning to read, becoming a good reader includes learning to read fluently (Gunning, 2020). Many beginning or poor readers do not recognize words automatically. Their processing capacity is consumed by the demands of word recognition, so they have less capacity to devote to comprehension of groupings of words as phrases or sentences. As their processing of words and passages becomes more automatic, it is said that their reading becomes more *fluent* (Dewitz & others, 2020). Also, children's vocabulary development plays an important role in the development of their reading comprehension (Vacca & others, 2018). And metacognitive strategies, such as learning to monitor one's reading progress, getting the gist of what is being read, and summarizing, also are fundamental to becoming a good reader (Zarger, Adams, & McDonald Connor, 2020).

Another important aspect of reading is the concept of "learning to read" versus "reading to learn." That is, while the first few years of schooling focus on teaching children to read, at some point it becomes important to move beyond the task of learning to read to actually using literacy experiences to learn new material from texts. This transition generally occurs at about the third grade, at which point there is less and less direct instruction on the act of reading *per se* and more emphasis on reading comprehension and on effectively extracting and understanding information from texts.

Writing Children's writing emerges out of their early scribbles, which appear at around 2 to 3 years of age (Hirsh-Pasek & Golinkoff, 2007). In early childhood, children's motor skills usually develop to the point that they can begin printing letters. Most 4-year-olds can print their first names. Five-year-olds can reproduce letters and copy several short words. They gradually learn to distinguish the distinctive characteristics of letters, such as whether the lines are curved or straight, open or closed. Through the early elementary grades, many children continue to reverse letters such as *b* and *d* and *p* and *q*. At this age, if other aspects of the child's development are normal, letter reversals do not predict literacy problems.

phonics approach A teaching approach built on the idea that reading instruction should teach basic rules for translating written symbols into sounds.

As they begin to write, children often invent spellings. Usually they base these spellings on the sounds of words they hear (Spandel, 2009).

Parents and teachers should encourage children's early writing but not be overly concerned about the formation of letters or spelling. Printing errors are a natural part of the child's growth. Corrections of spelling and printing should be selective and made in positive ways that do not discourage the child's writing and spontaneity.

What are some key strategies for teaching children how to write?
Liderina/Shutterstock

Like becoming a good reader, becoming a good writer takes many years and lots of practice (Graham & Rui, 2021). Children should be given many writing opportunities. As their language and cognitive skills improve with good instruction, so will their writing skills (Morrow, 2020). For example, developing a more sophisticated understanding of syntax and grammar serves as an underpinning for better writing. So do such cognitive skills as organization and logical reasoning. During their school years, students develop increasingly sophisticated methods of organizing their ideas. In early elementary school, they narrate and describe or write short poems. In late elementary and middle school, they can combine narration with reflection and analysis in projects such as book reports.

Monitoring one's writing progress is especially important in becoming a good writer (Graham & others, 2021). This includes being receptive to feedback and applying what one

learns in writing one paper to making the next paper better. In one study, Self-Regulated Strategy Development (SRSD) was implemented with second-grade teachers and their students who were at risk for writing failure (Harris, Graham, & Adkins, 2015). The students were taught a general planning strategy and general writing strategies (a catchy opening, effective vocabulary, clear organization, and an effective ending). The intervention produced positive results for story writing quality, motivation, and effort, as well as meaningful generalization to personal writing.

There are increasing concerns about students' writing competence (Graham & Rui, 2021; Vukelich & others, 2020). One study revealed that 70 to 75 percent of U.S. students in grades 4 through 12 are low-achieving writers (Persky, Dane, & Jin, 2003). Two studies—one of elementary school teachers, the other of high school teachers—raise concerns about the quality of writing instruction in U.S. schools (Gilbert & Graham, 2010; Kiuhara, Graham, & Hawken, 2009). The teachers in both studies reported that their college courses had inadequately prepared them to teach writing. The fourth- through sixth-grade teachers reported that they taught writing only 15 minutes a day. The high school teachers said that their writing assignments infrequently involved analysis and interpretation, and almost 50 percent of them had not assigned any multi-paragraph writing assignments in the span of one month's time.

The metacognitive strategies involved in being a competent writer are linked with those required to be a competent reader because the writing process involves competent reading and rereading during composition and revision (Longa & Graham, 2020). Further, researchers have found that strategy instruction involving planning, drafting, revising, and editing improve older elementary school children's metacognitive awareness and writing competence (Graham & Harris, 2021).

As with reading, teachers play a critical role in students' development of writing skills (Graham & Rui, 2021). Effective writing instruction provides guidance about planning, drafting, and revising, not only in elementary school but through the college years (Mayer, 2008). A meta-analysis revealed that the following interventions were the most effective in improving fourth- through twelfth-grade students' writing quality: (1) strategy instruction, (2) summarization, (3) peer assistance, and (4) setting goals (Graham & Perin, 2007).

Second-Language Learning and Bilingualism Are there sensitive periods in learning a second language? That is, if individuals want to learn a second language, how important is the age at which they begin to learn it? For many years, it was claimed that if individuals did not learn a second language prior to puberty they would never reach native-language speakers' proficiency in the second language (Johnson & Newport, 1991). However, research indicates a more complex conclusion: Sensitive periods likely vary across different language systems (Thomas & Johnson, 2008). Thus, for late language learners such as adolescents and adults, new vocabulary is easier to learn than new sounds or new grammar (Neville, 2006). For example, children's ability to pronounce words with a native-like accent in a second language typically decreases with age, with an especially sharp drop occurring after age 10 to 12. Also, adults tend to learn a second language faster than children do, but their final level of second-language attainment is not as high as children's. And the way children and adults learn a second language differs somewhat. Compared with adults, children are less sensitive to feedback, less likely to use explicit strategies, and more likely to learn a second language from large amounts of input (Thomas & Johnson, 2008).

Children in many countries learn more than one language. Shown here is author John Santrock observing a preschool in Fes, Morocco, in 2015. The young children sang songs in three different languages—Arabic, French, and English. *Do you think children in the United States should learn more than one language?*
Courtesy of Dr. John Santrock

Students in the United States lag far behind their counterparts in many developed countries in learning a second language. For example, in Russia, schools have ten grades, called *forms*, which roughly correspond to the twelve grades in American schools. Russian children begin school at age 7 and begin learning English in the third form. Because of this emphasis on teaching English, most Russian citizens under the age of 40 today are able to speak at least some English. The United States is the only technologically advanced Western nation that does not have a national foreign-language requirement at the high school level, even for students in rigorous academic programs.

Some aspects of children's language skills are transferred more easily to the second language than others (Pace & others, 2021). Children who are fluent in two languages perform better than their single-language counterparts on tests of control of attention, concept formation, analytical reasoning, inhibition, cognitive flexibility, cognitive complexity, and cognitive monitoring (Bialystok, 2011,

2015, 2017). In a recent analysis across a number of countries, bilingual children consistently demonstrated better executive function than non-bilingual children (Schirmbeck, Rao, & Maehler, 2020). In addition, a recent study of 3-year-olds found that shared book reading at home and school in a second language not only improved their second-language learning but also the perspective taking emphasized in the shared reading program increased their ability to shift perspectives and understand others' emotional states (Grover & others, 2020). And a recent study of Chinese children found that bilingual children who were learning English as a foreign language outperformed monolingual Chinese children on an attention task and had higher activation of their prefrontal cortex (Li & others, 2019).

Thus, in the research just described, it appears that bilingualism is linked to positive outcomes for children's cognitive development (Antovich & Graf Estes, 2020; Tao & others, 2021). However, some recent studies have not found cognitive advantages for bilingual children (Dick & others, 2019; Donnelly, Brooks, & Homer, 2019). Thus, a firm conclusion about cognitive outcomes of bilingualism awaits further research.

An especially important developmental question that many parents of infants and young children have is whether to teach them two languages simultaneously or just teach one language at a time to avoid confusion. The answer is that teaching infants and young children two languages simultaneously (as when a mother's native language is English and her husband's is Spanish) has numerous benefits and few drawbacks (Brito, 2021).

A different type of bilingualism occurs when immigrant children have learned only their native language at home and then must learn the main language of their new country at school. For example, in the United States, many immigrant children go from being monolingual in their home language to bilingual in that language and in English, only to end up becoming monolingual speakers of English. This is called *subtractive bilingualism*, and it can have negative effects on children, who often become ashamed of their home language.

Another question involving bilingualism involves the many immigrant children in the United States who mainly speak their native language at home with little opportunity to speak English before they enter school. In a recent study, Virginia Marchman and her colleagues (2020) found that stronger Spanish language skills at 2 years of age were linked to better English language skills as well as maintenance of good language skills at 4½ years of age. These findings indicate that families who primarily speak Spanish should engage in activities that develop children's competence in Spanish while also encouraging opportunities to learn English.

Also, a current controversy related to bilingualism involves the millions of U.S. children who come from homes in which English is not the primary language and then later at school must also learn English (Diaz-Rico, 2020). What is the best way to teach these English language learners (ELLs), many of whom in the United States are from immigrant families living in poverty?

A first- and second-grade bilingual English-Cantonese teacher instructs students in Chinese in Oakland, California. *What have researchers found about the effectiveness of bilingual education?*
Elizabeth Crews

ELLs have been taught in one of two main ways: (1) instruction in English only, or (2) a *dual-language* (formerly called *bilingual*) approach that involves instruction in their home language and English (Herrell & Jordan, 2020). In a dual-language approach, instruction is given in both the ELL child's home language and English for varying amounts of time at certain grade levels. One of the arguments in favor of the dual-language approach is the research discussed earlier demonstrating that bilingual children have more advanced information-processing skills than monolingual children do (Bialystok, 2017).

If a dual-language strategy is used, too often it has been thought that immigrant children need only one or two years of this type of instruction. However, in general it takes immigrant children approximately three to five years to develop speaking proficiency and seven years to develop reading proficiency in English (Hakuta, Butler, & Witt, 2001). Also, immigrant children vary in their ability to learn English (Esposito & others, 2018). Children who come from lower socioeconomic backgrounds have more difficulty than those from higher socioeconomic backgrounds (Hoff & Place, 2013). Thus, especially for immigrant children from low

connecting with careers

Salvador Tamayo, Teacher of English Language Learners

Salvador Tamayo is an ELL fifth-grade teacher at Turner Elementary School in West Chicago. He received a National Educator Award from the Milken Family Foundation for his work in educating ELLs. Tamayo is especially adept at integrating technology into his ELL classes. He and his students have created several award-winning Web sites about the West Chicago City Museum, the local Latinx community, and the history of West Chicago. His students developed an "I Want to Be an American Citizen" Web site to assist family and community members in preparing for the U.S. Citizenship Test. Tamayo also teaches an ELL class at Wheaton College.

Salvador Tamayo instructs students in his bilingual education class.
Courtesy of Salvador Tamayo

socioeconomic backgrounds, more years of dual-language instruction may be needed than they currently are receiving.

What have researchers found regarding outcomes of ELL programs? Drawing conclusions about the effectiveness of ELL programs is difficult because of variations across programs in the number of years they are in effect, type of instruction, quality of schooling other than ELL instruction, teachers, children, and other factors. Further, no effective experiments have been conducted that compare bilingual education with English-only education in the United States (Snow & Kang, 2006). Some experts have concluded that the quality of instruction is more important in determining outcomes than the language in which it is delivered (Lesaux & Siegel, 2003).

Nonetheless, other experts, such as Kenji Hakuta (2001, 2005), support the combined home language and English approach because (1) children have difficulty learning a subject when it is taught in a language they do not understand; and (2) when both languages are integrated in the classroom, children learn the second language more readily and participate more actively. In support of Hakuta's view, most large-scale studies have found that the academic achievement of ELLs is higher in dual-language programs than in English-only programs. To read about the work of one ELL teacher, see the *Connecting with Careers* profile.

ADOLESCENCE

Language development during adolescence includes greater sophistication in the use of words. With increasing ability to engage in abstract thinking, adolescents are much better than children at analyzing the role a word plays in a sentence.

Adolescents also develop more subtle abilities with words. They make strides in understanding **metaphor,** which is an implied comparison between unlike things. For example, individuals "draw a line in the sand" to indicate a nonnegotiable position; a political campaign is said to be a marathon, not a sprint; a person's faith is shattered. And adolescents become better able to understand and to use **satire,** which is the use of irony, derision, or wit to expose folly or wickedness. Caricatures are an example of satire. More advanced logical thinking also allows adolescents, from about 15 to 20 years of age, to understand complex literary works.

Most adolescents are also much better writers than children are. They are better at organizing ideas before they write, at distinguishing between general and specific points as they write, at stringing together sentences that make sense, and at organizing their writing into an introduction, body, and concluding remarks. Adolescents also are better than children at persuasive writing in which they have to take a position and try to convince the reader of the accuracy and strength of their position (Nippold, 2016).

metaphor An implied comparison between two unlike things.

satire The use of irony, derision, or wit to expose folly or wickedness.

What are some changes in language development in adolescence?
Ian Shaw/Alamy Stock Photo

Everyday speech changes during adolescence, and "part of being a successful teenager is being able to talk like one" (Berko Gleason, 2005, p. 9). Young adolescents often speak a **dialect** with their peers that is characterized by jargon and slang (Cave, 2002). A dialect is a variety of language that is distinguished by its vocabulary, grammar, or pronunciation. For example, when meeting a friend, instead of saying hello, a young adolescent might say, "Sup?" ("What's up?"). Nicknames that are satirical and derisive ("Stilt," "Refrigerator," "Spaz") also characterize the dialect of young adolescents. Such labels might be used to show that one belongs to the group and to reduce the seriousness of a situation (Cave, 2002).

ADULTHOOD AND AGING

Most research on language development has focused on infancy and childhood. It is generally thought that for most of adulthood individuals maintain their language skills.

In the adolescent and adult years, the development of an identity—a sense of who one is—is an important life task. A distinct personal linguistic style is part of one's special identity (Berko Gleason, 2009). Further psychological goals of early adulthood that call for expanded linguistic skills include entering the world of work and establishing intimate relations with others.

Language development during the adult years varies greatly among individuals, depending on such factors as level of education and social and occupational roles. Actors, for instance, must learn not only to speak in a way that can be heard by large audiences but also to speak the words of others using varying voices and regional dialects. Working people learn the special tones of voice and terminology associated with their own occupational language (Berko Gleason, 2005, p. 9).

The vocabulary of individuals often continues to increase throughout most of the adult years, at least until late adulthood (Schaie, 2012; Singh-Manoux & others, 2012). Many older adults "maintain or improve their knowledge of words and word meanings" (Burke & Shafto, 2004, p. 24).

What are some differences in the ways older and younger adults communicate?
Tom Grill/JGI/Blend Images/Getty Images

In late adulthood, however, some decrements in language may appear (Payne & Federmeier, 2018). Among the most common language-related complaints reported by older adults is difficulty in retrieving words to use in conversation and in understanding spoken language in certain contexts (Clark-Cotton, Williams, & Goral, 2007). These often involve the *tip-of-the-tongue phenomenon (TOT)*, in which individuals are confident that they can remember something but just can't quite seem to retrieve it from memory (James & others, 2018). Older adults also report that in less than ideal listening conditions they can have difficulty in understanding speech. This difficulty is most likely to occur when speech is rapid, when competing stimuli are present (a noisy room, for example), and when they can't see their conversation partner (in a telephone conversation, for example). The difficulty in understanding speech may be due to hearing loss (Benichov & others, 2012). In general, though, most language skills decline little among older adults who are healthy (Clark-Cotton & others, 2007; Thornton & Light, 2006).

Some aspects of the phonological skills of older adults differ from those of younger adults (Robert & Mathey, 2018). Older adults' speech is typically lower in volume, slower, less precisely articulated, and less fluent (more pauses, fillers, repetition, and corrections). Despite these age differences, the speech skills of most older adults are adequate for everyday communication. One study found that when retelling a story, older adults were more likely than younger adults to compress discourse and less likely to improve the cohesiveness of their narratives (Saling, Laroo, & Saling, 2012). Also, a recent study of 19- to 75-year-olds confirmed that older adults were more likely to have difficulties in narrative discourse than younger age groups (Babaei, Ghayoumi-Anaraki, & Mahmoodi-Bakhtiari, 2019).

Nonlanguage factors may be responsible for some of the declines in language skills that occur in older adults (Obler, 2009). Slower information-processing speed and a decline in working memory, especially in regard to keeping information in mind while processing, likely contribute to reduced language efficiency in older adults (Salthouse, 2013). For example, a recent study found that the lower working memory capacity of older adults compared with younger adults impaired their comprehension of sentences (Sung & others, 2017).

Language does change among individuals with Alzheimer disease (Resende & others, 2020). Word-finding/generating difficulties are one of the earliest symptoms of Alzheimer disease (Haugrud, Crossley, & Vrbancic, 2011). Individuals with Alzheimer disease especially have difficulty on tests of semantic verbal fluency, in which they have to say as many words as possible in a category (fruits or animals, for example) in a given time, typically one minute (Weakley & Schmitter-Edgecombe, 2014). Most individuals with the disease do retain much

dialect A variety of language that is distinguished by its vocabulary, grammar, or pronunciation.

of their ability to produce well-formed sentences until the late stages of the disease. Nonetheless, they do make more grammatical errors than older adults without the disease (Huang, Meyer, & Federmeier, 2012).

Recently researchers began exploring the possibility that bilingualism might delay the onset of Alzheimer disease (Berkes & others, 2021; Paulavicius & others, 2020). One study found that the onset of Alzheimer disease occurred 4.5 years later in bilingual older adults (Alladi & others, 2013). Another study revealed that the onset of symptoms and first office visit for Alzheimer disease occurred several years later for bilingual than for monolingual older adults (Bialystok & others, 2014). These results led Ellen Bialystok and her colleagues (2016) to conclude that being bilingual may be one of the best ways to delay the onset of Alzheimer disease by as much as four to five years. Also, in a recent study of individuals with mild cognitive impairment, those who were bilingual had better verbal memory than monolingual individuals (Rosselli & others, 2019). In addition, a recent study indicated a bilingual advantage for the alerting subcomponent of attention (Dash & others, 2019).

Based on these research findings, might learning a second language as an older adult be beneficial? In a recent study of 59- to 79-year-olds, a 4-month-long second language program produced improvements in global cognitive functioning and connectivity among different regions of the brain's frontal and parietal lobes (Bubbico & others, 2019). It is not yet clear why the advantage occurs for bilingual older adults, but one explanation might be better executive function (Gasquoine, 2016). For example, a recent study found that bilingual Alzheimer patients had better neural network functioning, especially in the neural network involving executive function, than did monolingual Alzheimer patients (Perani & others, 2017).

3 Biological and Environmental Influences

LG3 Discuss the biological and environmental contributions to language skills.

Biological Influences | Environmental Influences | An Interactionist View of Language

We have described how language develops, but we have not explained what makes this amazing development possible. Everyone who uses language in some way "knows" its rules and has the ability to create an infinite number of words and sentences. Where does this knowledge come from? Is it the product of biology? Or is language learned and influenced by experiences?

BIOLOGICAL INFLUENCES

Some language scholars view the remarkable similarities in how children acquire language all over the world, despite the vast variation in language input they receive, as strong evidence that language has a biological basis. What role did evolution play in the biological foundations of language?

Broca's area An area of the brain's left frontal lobe that is involved in producing words.

Wernicke's area An area of the brain's left hemisphere that is involved in language comprehension.

aphasia A loss or impairment of language processing resulting from damage to Broca's area or Wernicke's area.

language acquisition device (LAD) Chomsky's term that describes a biological endowment that enables the child to detect certain features and rules of language, including phonology, syntax, and semantics.

In the wild, chimps communicate through calls, gestures, and expressions, which evolutionary psychologists believe might be the roots of true language.
Andrey Gudkov/123RF

developmental **connection**
Brain Development
Much of our language processing takes place in the brain's left hemisphere. Connect to "Physical Development and Biological Aging."

Evolution and the Brain's Role in Language

The ability to speak and understand language requires a certain vocal apparatus as well as a nervous system with certain capabilities. The nervous system and vocal apparatus of humanity's predecessors changed over hundreds of thousands or millions of years (Cassidy, 2021). With advances in the nervous system and vocal structures, *Homo sapiens* went beyond the grunting and shrieking of other animals to develop speech (Berecz & others, 2020). Although estimates vary, many experts hold that humans acquired language about 100,000 years ago, which in evolutionary time represents a very recent acquisition. Language gave humans an enormous edge over other animals and increased the chances of human survival (de Boer & Thompson, 2018).

As further support for the biological foundations of language, there is evidence that specific regions of the brain are predisposed to be used for language (Berezutskaya & others, 2020). Two regions involved in language were first discovered in studies of brain-damaged individuals: **Broca's area,** a region of the left frontal lobe of the brain that is involved in producing words (Pirau & Lui, 2020), and **Wernicke's area,** a region of the brain's left hemisphere that is involved in language comprehension (Jancke, Liem, & Merillat, 2021) (see Figure 7). Damage to either of these areas produces types of **aphasia,** which is a loss or impairment of language processing. Individuals with damage to Broca's area have difficulty producing words correctly, while individuals with damage to Wernicke's area have poor comprehension and often produce fluent but incomprehensible speech.

FIGURE **7**

BROCA'S AREA AND WERNICKE'S AREA. Broca's area is located in the frontal lobe of the brain's left hemisphere, and it is involved in the control of speech. Wernicke's area is a portion of the left hemisphere's temporal lobe that is involved in understanding language. *How does the role of these areas of the brain relate to lateralization, discussed in the chapter on "Physical Development and Biological Aging"?*
(*photo*): Swissmacky/Shutterstock

Chomsky's Language Acquisition Device (LAD)

Linguist Noam Chomsky (1957) proposed that humans are biologically prewired to learn language at a certain time and in a certain way. He said that children are born into the world with a **language acquisition device (LAD),** a biological endowment that enables the child to detect certain features and rules of language, including phonology, syntax, and semantics. Children are endowed by nature with the ability to detect the sounds of language, for example, and to follow rules such as those for forming plurals and asking questions.

Chomsky's LAD is a theoretical construct, not a physical part of the brain. Is there evidence for the existence of a LAD? Supporters of

the LAD concept cite the uniformity of language milestones across languages and cultures, evidence that children create language even in the absence of well-formed input, and biological foundations of language. But, as we will see, critics argue that even if infants have something like a LAD, it cannot fully explain the process of language acquisition.

ENVIRONMENTAL INFLUENCES

Our coverage of environmental influences on language development in infancy focuses on the important role of social interaction, including child-directed speech and other caregiver strategies.

> The linguistics problems children have to solve are always embedded in personal and interpersonal contexts.
>
> —LOIS BLOOM
> *Contemporary Psychologist, Columbia University*

The Role of Social Interaction Language is not learned in a social vacuum. Most children are bathed in language from a very early age, unlike the Wild Boy of Aveyron, who never learned to communicate effectively, having lived in social isolation for years. Thus, social cues play an important role in infant language learning (Custode & Tamis-LeMonda, 2020).

The support and involvement of caregivers and teachers greatly facilitate a child's language learning (Levine, Hirsh-Pasek, & Golinkoff, 2021). In one study, both full-term and preterm infants who heard more caregiver talk based on all-day recordings at 16 months of age had better language skills (receptive and expressive language, language comprehension) at 18 months of age (Adams & others, 2018). Also, in a recent study, conversational turn counts at 18 to 24 months were linked to receptive and expressive vocabulary development 10 years later (Gilkerson & others, 2018).

And in another study, when mothers immediately smiled and touched their 8-month-old infants after they babbled, the infants subsequently made more complex speech-like sounds than when mothers responded to their infants in a random manner (Goldstein, King, & West, 2003) (see Figure 8).

Michael Tomasello (2011, 2014, 2020) stresses that young children are intensely interested in their social world and that early in their development they can understand the intentions of other people. His emphasizes that children learn language in specific contexts. For example, when a toddler and a father are jointly focused on a book, the father might point to a picture of a bird and say, "See the birdie." In this case, even a toddler understands that the father intends to name something and knows to look in the direction of the pointing. Through this kind of joint attention, early in their development children are able to use their social skills to acquire language (Piazza & others, 2020). One study revealed that joint attention at 12 and 18 months predicted language skills at 24 months (Mundy & others, 2007). Also, in a study involving joint attention, infants' eye-gaze behaviors during Spanish tutoring sessions at 9.5 to 10.5 months predicted their second-language phonetic learning at 11 months, indicating a strong influence of social interaction at the earliest ages of learning a second language (Conboy & others, 2015).

Thus, social experiences play an important role in infant language learning (Levine, Hirsh-Pasek, & Golinkoff, 2021). Joint engagement and relevant responsiveness by a social partner predict better growth in language later in development, possibly because they improve the infant's mapping process between words and the world (Tamis-LeMonda, Kurchirko, & Song, 2014).

FIGURE **8**

SOCIAL INTERACTION AND BABBLING. One study focused on two groups of mothers and their 8-month-old infants (Goldstein, King, & West, 2003). One group of mothers was instructed to smile and touch their infants immediately after the babies cooed and babbled; the other group was also told to smile and touch their infants but in a random manner, unconnected to sounds the infants made. The infants whose mothers immediately responded in positive ways to their babbling subsequently made more complex, speech-like sounds, such as *da* and *gu*. The research setting for this study, which underscores how important caregivers are in the early development of language, is shown here.
Courtesy of Dr. Michael Goldstein

Given that social interaction is a critical component for infants to learn language effectively, might they also be able to learn language effectively through television and videos? Researchers have found that infants and young children cannot effectively learn language (phonology or words) from television or videos (Zosh & others, 2017). In fact, a study of toddlers found that frequent viewing of television increased the risk of delayed language development (Lin & others, 2015). Thus, just hearing language is not enough, even when infants seemingly are fully engaged in the experience.

The American Academy of Pediatrics (APA) (2016) concluded that from 15 months to 2 years of age, evidence indicates that if parents co-watch educational videos with their infant and communicate with the infant about what they are viewing, it can benefit the infant's development. This suggests that when parents treat an educational video or app like a picture book, infants can benefit from it. However, the APA still recommends no watching of videos alone when children are younger than 18 months of age.

developmental **connection**

Screen Time

Researchers have found that infants and young children who have higher TV and DVD exposure have more difficulty with spoken language. Connect to "Peers and the Sociocultural World."

What are some good strategies for parents and teachers to use to improve infants' and young children's language development?
Roberto Westbrook/Getty Images

Child-Directed Speech and Other Caregiver Strategies One intriguing component of the young child's linguistic environment is **child-directed speech** (also referred to as *parentese*), which is language spoken in a higher pitch, slower tempo, and more exaggerated intonation than normal, with simple words and sentences (Conica, Nixon, & Quigley, 2020; Nencheva, Piazza, & Lew-Williams, 2021). It is hard to use child-directed speech when not in the presence of a baby. As soon as you start talking to a baby, though, you shift into child-directed speech. Much of this is automatic and something most parents are not aware they are doing. As mentioned previously, even 4-year-olds speak in simpler ways to 2-year-olds than to their 4-year-old friends. Child-directed speech serves the important functions of capturing the infant's attention, maintaining communication and social interaction between infants and caregivers, and providing infants with information about their native language by heightening differences from speech directed to adults (Golinkoff & others, 2015).

In a recent study, parent coaching at 6, 10, and 14 months of age that involved child-directed speech, back-and-forth interactions, and parentese speech style increased the infants' conversational turns and language skills (production of words, for example) at 18 months of age (Ferjan Ramirez, Lytle, & Kuhl, 2020). In other research, child-directed speech in a one-to-one social context at 11 to 14 months was linked to greater word production at 2 years of age than standard speech and speech in a group setting (Ramirez-Esparza, Garcia-Sierra, & Kuhl, 2017). Another study of low-SES Spanish-speaking families revealed that infants who experienced more child-directed speech were better at processing words in real time and had larger vocabularies at 2 years of age (Weisleder & Fernald, 2013).

Adults often use strategies other than child-directed speech to enhance the child's acquisition of language, including recasting, expanding, and labeling:

- **Recasting** takes place when an adult rephrases something the child has said if the child's statement lacks the appropriate morphology or contains some other error. The adult restates the child's immature utterance in the form of a fully grammatical sentence. For example, if a 2-year-old says, "Dog bark," the adult may respond by saying, "Oh, you heard the dog barking!" The adult sentence provides an acknowledgment that the child was heard and then adds the morphology /ing/ and the article (the) that the child's utterance lacked.
- **Expanding** involves adding information to a child's incomplete utterance. For example, if a child says, "Doggie eat," the parent might reply, "Yes, the dog is eating his food out of his special dish."
- **Labeling** involves naming objects that children seem interested in. Young children are forever being asked to identify the names of objects. Roger Brown (1968) called this "the original word game." Children want to learn more than the names of objects, though; they often want information about the object as well.

Parents use these strategies naturally and in meaningful conversations. Parents do not (and should not) use any deliberate method to teach their children to talk, even for children who are slow in learning language. Children usually benefit when parents guide their children's discovery of language rather than overloading them with language.

Infants, toddlers, and young children also benefit when adults read books to and with them (shared reading) (Thompson, 2020). In one study, reading daily to children at 14 to 24 months of age was positively related to the children's language and cognitive development at 36 months of age (Raikes & others, 2006). Further, in a recent study, the more parents engaged in parent-child book reading interactions from 1 to 2.5 years of age, the better their children's language development was in terms of receptive vocabulary, reading comprehension, and motivation to read in elementary school (Demir-Lira & others, 2019). Also, a recent study of 9- to 18-month-old infants found that book sharing resulted in more parent talk, child talk, and interactions than other language activities (toy play, personal care, and mealtime, for example) (Clemens & Kegel, 2021). And a recent meta-analysis concluded that shared picture book reading was linked to children having better expressive and receptive language (Dowdall & others, 2020).

Remember, parental encouragement of language development during interactions with their children, not drill and practice, is the key. Language development is not a simple matter

child-directed speech Language spoken in a higher pitch than normal, with simple words and sentences.

recasting An adult's rephrasing of a child's statement that might lack the appropriate morphology or contain some other error. The adult restates the child's immature utterance in the form of a fully grammatical sentence.

expanding Adding information to the child's incomplete utterance.

labeling Naming objects that children seem interested in.

connecting development to life

How Parents Can Facilitate Infants' and Toddlers' Language Development

Linguist Naomi Baron (1992) in *Growing Up with Language,* developmental psychologists Roberta Golinkoff and Kathy Hirsh-Pasek (1999) in *How Babies Talk,* and more recently Ellen Galinsky (2010) in *Mind in the Making,* provided ideas to help parents facilitate their infants' and toddlers' language development. A summary of their ideas follows:

- *Be an active conversational partner*. Talk to your baby from the time it is born. Initiate conversation with the baby. If the baby is in a full-day child-care program, ensure that the baby receives adequate language stimulation from adults.
- *Talk at a slowed-down pace and don't worry about how you sound to other adults when you talk to your baby.* Talking more slowly will make it easier for your baby to detect words in the sea of sounds they experience. Babies enjoy and attend to the high-pitched sound of child-directed speech.
- *Narrate your daily activities to the baby as you do them.* For example, talk about how you are putting the baby in her highchair for lunch, ask her what she would like to eat, and so on.
- *Use parent-look and parent-gesture, and name what you are looking at*. When you want your child to pay attention to something, look at it and point to it. Then name it—for example, by saying, "Look, Alex, there's an airplane."
- *When you talk with infants and toddlers, be simple, concrete, and repetitive*. Don't try to talk to them in abstract, high-level ways and think you have to say something new or different all of the time. Using familiar words often will help them remember the words.
- *Play games*. Use word games like peek-a-boo and pat-a-cake to help infants learn words.
- *Remember to listen*. Since toddlers' speech is often slow and laborious, parents are often tempted to supply words and thoughts for them. Be patient and let toddlers express themselves, no matter how painstaking the process is or how great a hurry you are in.
- *Expand and elaborate language abilities and horizons with infants and toddlers*. Ask questions that encourage answers other than "Yes'' and "No.'' Actively repeat, expand, and recast the utterances. Your toddler might say, "Dada." You could respond by asking, "Where's Dada?" and then suggesting, "Let's go find him."
- *Adjust to your child's idiosyncrasies instead of working against them*. Many toddlers have difficulty pronouncing words and making themselves understood. Whenever possible, make toddlers feel that they are being understood.
- *Resist making normative comparisons*. Be aware of the ages at which your child reaches specific milestones (such as the first word, first 50 words, and so on), but do not measure this development rigidly against that of other children. Such comparisons can bring about unnecessary anxiety.

It is a good idea for parents to begin talking to their babies at the start. The best language teaching occurs when the talking is begun before the infant becomes capable of intelligible speech. *What are some other guidelines for parents to follow in helping their infants and toddlers develop their language skills?*
Tetra Images/Getty Images

The first suggestion for parents of infants is to "be an active conversational partner." What did you learn earlier in this chapter about the amount of conversation mothers have with their infants? Does the amount of conversation or the mother's literacy skills and vocabulary diversity have a stronger positive effect on infants' vocabulary?

of imitation and reinforcement. To read further about ways that parents can facilitate children's language development, see the *Connecting Development to Life* interlude.

Our discussion of environmental influences on language development has focused mainly on parents. However, children interact with many other people who can influence their language development, including teachers and peers. A study of more than 1,800 4-year-olds focused on ways in which peers might influence children's language development (Mashburn & others, 2009). In this study, peers' expressive language abilities were positively linked with young children's receptive and expressive language development.

AN INTERACTIONIST VIEW OF LANGUAGE

If language acquisition depended only on biology, then Genie and the Wild Boy of Aveyron (discussed at the beginning of the chapter) should have talked without difficulty. A child's experiences influence language acquisition (Levine, Hirsh-Pasek, & Golinkoff, 2021). But we have seen that language does have strong biological foundations as well (Cassidy, 2021). No matter how much you converse with a dog, it won't learn to talk.

An interactionist view emphasizes that both biology and experience contribute to language development. This interaction of biology and experience can be seen in the variations in the acquisition of language. Children vary in their ability to acquire language, and this variation cannot be readily explained by differences in environmental input alone. However, virtually every child benefits enormously from opportunities to talk and be talked with (Brito, 2021). Children whose parents and teachers provide them with a rich verbal environment show many positive outcomes (Collins & Toppelberg, 2021). Parents and teachers who pay attention to what children are trying to say, expand their children's utterances, read to them, and label things in the environment, are providing valuable, if unintentional, benefits (Odijk & Gillis, 2021).

LG3 Discuss the biological and environmental contributions to language skills.

Review

- What are the biological foundations of language?
- What are the environmental aspects of language?
- How does an interactionist view describe language?

Connect

- Relate what you learned about the nature-nurture debate to understanding biological and environmental influences on the development of language skills.

Reflect *Your Own Personal Journey of Life*

- If and when you become a parent, how should you respond to your child's grammar when conversing with the child? Will you allow mistakes to continue and assume that your young child will grow out of them, or will you closely monitor your young child's grammar and correct mistakes whenever you hear them? Explain.

reach your **learning goals**

Language Development

1 What Is Language?

LG1 Define language and describe its rule systems.

Defining Language

Language's Rule Systems

- Language is a form of communication, whether spontaneous, written, or signed, that is based on a system of symbols. Language consists of all the words used by a community and the rules for varying and combining them. Infinite generativity is the ability to produce an endless number of meaningful sentences using a finite set of words and rules.
- The main rule systems of language are phonology, morphology, syntax, semantics, and pragmatics. Phonology is the sound system of a language, including the sounds used and the sound sequences that may occur in the language. Morphology refers to units of meaning in word formation. Syntax is the way words are combined to form acceptable phrases and sentences. Semantics involves the meaning of words and sentences. Pragmatics is the appropriate use of language in different contexts.

2 How Language Develops

LG2 Describe how language develops through the life span.

Infancy

- Among the milestones in infant language development are crying (birth), cooing (2 to 4 months), understanding first word (5 months), babbling (6 months), making the transition from universal linguist to language-specific listener (6 to 12 months), using gestures (8 to 12 months), detecting word boundaries (8 months), first word spoken (13 months), vocabulary spurt (18 months), rapid expansion of understanding words (18 to 24 months), and two-word utterances (18 to 24 months).

Early Childhood

- Advances in phonology, morphology, syntax, semantics, and pragmatics continue in early childhood. The transition to complex sentences begins between 2 and 3 years and continues through the elementary school years. Fast mapping provides one explanation for how rapidly young children's vocabulary develops.

Middle and Late Childhood

- In middle and late childhood, children become more analytical and logical in their approach to words and grammar. Current debate involving how to teach children to read focuses on the whole-language approach versus the phonics approach. Researchers have found strong evidence that the phonics approach should be used in teaching children to read but that children also benefit from the whole-language approach.
- Children's writing emerges out of scribbling. Advances in children's language and cognitive development provide the underpinnings for improved writing.
- Recent research indicates a complex conclusion about whether there are sensitive periods in learning a second language. Children who are fluent in two languages have more advanced information-processing skills.
- Instruction for English language learners (ELLs) has taken one of two main forms: (1) instruction in English only, or (2) dual-language instruction in the child's home language and English. The majority of large-scale research studies have found a higher level of academic achievement when the dual-language approach is used.

Adolescence

- In adolescence, language changes include more effective use of words; improvements in the ability to understand metaphor, satire, and adult literary works; and improvements in writing.

Adulthood and Aging

- For many individuals, knowledge of words and word meanings continues unchanged or may even improve in later adulthood. However, some decline in language skills may occur in retrieving words for use in conversation, in understanding speech, in phonological skills, and in some aspects of discourse. These changes in language skills in older adults likely occur as a consequence of declines in memory or in speed of processing information, or as a result of disease.

3 Biological and Environmental Influences

LG3 Discuss the biological and environmental contributions to language skills.

Biological Influences

- In evolution, language gave humans an enormous edge over other animals and increased their chances of survival.
- A substantial portion of language processing occurs in the brain's left hemisphere, with Broca's area and Wernicke's area being important left-hemisphere locations.
- Chomsky argues that children are born with the ability to detect basic features and rules of language. In other words, they are biologically prepared to learn language with a prewired language acquisition device (LAD).

Environmental Influences

- The behaviorists' view of language development—that children acquire language as a result of reinforcement—has not been supported. Adults help children acquire language through child-directed speech, recasting, expanding, and labeling.
- Environmental influences are demonstrated by differences in the language development of children as a consequence of being exposed to different language environments in the home. Parents should talk extensively with an infant, especially about what the baby is attending to. Social cues play an important role in language learning.

An Interactionist View of Language

- The interactionist view emphasizes the contributions of both biology and experience in language development.

Socioemotional Processes and Development

Generations will depend on the ability of all procreating individuals to face their children.

—Erik Erikson
Danish-born American Psychoanalyst, 20th Century

As children develop, they need "the meeting eyes of love." They split the universe into two halves: "me and not me." They juggle the need to curb their will with becoming what they can freely be. Children and youth want to fly but discover that first they have to learn to stand and walk and climb and dance. Adolescents try on one face after another, searching for a face of their own. As adults age, they seek satisfaction in their emotional lives and search for the meaning of life. This section contains four chapters: "Emotional Development and Attachment," "The Self, Identity, and Personality," "Gender and Sexuality," and "Moral Development, Values, and Religion."

preview

For many years, emotion was neglected in the study of life-span development. Today, emotion is increasingly important in conceptualizations of development. For example, even as infants, individuals show different emotional styles, display varying temperaments, and begin to form emotional bonds with their caregivers. In this chapter, we study how temperament and attachment change across the life span. But first, we examine emotion itself, exploring the functions of emotions in people's lives and the development of emotion from infancy through late adulthood.

1 Exploring Emotion

LG1 Discuss basic aspects of emotion.

What Are Emotions? | Emotion Regulation | Emotional Competence

Imagine your life without emotion. Emotion is the color and music of life, as well as the tie that binds people together. How do psychologists define and classify emotions, and why are they important to development?

Blossoms are scattered by
the wind
And the wind cares nothing, but
The blossoms of the heart,
No wind can touch.

—YOSHIDA KENKO
Buddhist Monk, 14th Century

WHAT ARE EMOTIONS?

For our purposes, we will define **emotion** as feeling, or affect, that occurs when a person is in a state or an interaction that is important to him or her, especially to his or her well-being. In infancy, emotions have important roles in (1) communication with others and (2) behavioral organization. Through emotions, infants communicate important aspects of their lives such as joy, sadness, interest, and fear (Mitsven & others, 2021). In terms of behavioral organization, emotions influence children's social responses and adaptive behavior as they interact with others in their world (Thompson & Waters, 2020).

When we think about emotions, a few dramatic feelings such as rage or glorious joy spring to mind. But emotions can be subtle as well, such as uneasiness in a new situation or the contentment a mother feels when she holds her baby. Psychologists classify the broad range of emotions in many ways, but almost all classifications designate an emotion as either positive or negative. Positive emotions include enthusiasm, joy, and love. Negative emotions include anxiety, anger, guilt, and sadness.

Emotions are influenced by biological foundations, cognitive processes, and a person's experiences (Aktar & Perez-Edgar, 2021; Cassidy, 2021). Biology's importance to emotion also is apparent in the changes in a baby's emotional capacities (Raineki & others, 2019). Certain regions of the brain that develop early in life (such as the brain stem, hippocampus, limbic system, and amygdala) play a role in distress, excitement, and rage, and even infants display these emotions (Banihashemi & others, 2020; Richards & Conte, 2021). But, as we discuss later in the chapter, infants only gradually develop the ability to regulate their emotions, and this ability is linked to the gradual maturation of frontal regions of the cerebral cortex that can exert control over other areas of the brain (Bell & Broomell, 2021).

Cognitive processes, both in immediate "in the moment" contexts and across childhood development, influence children's emotional development (Bornstein & Esposito, 2021; McCrae & Zarolia, 2021). Attention toward or away from an experience can influence children's emotional responses. For example, children who can distract themselves from a stressful encounter show a lower level of negative affect in the context and less anxiety over time (Crockenberg & Leerkes, 2006). Also, as children become older, they develop cognitive strategies for controlling their emotions and become more adept at modulating their emotional arousal (Cooley & others, 2020).

Biological evolution has endowed human beings with the capacity to be *emotional*, but cultural embeddedness and relationships with others provide diversity in emotional experiences (Dagan & Sagi-Schwartz, 2021; Muhlenbeck & others, 2020). Emotional development and coping with stress are influenced by whether children have been maltreated or neglected by

emotion Feeling, or affect, that occurs when a person is engaged in an interaction that is important to him or her, especially to his or her well-being.

How do Japanese mothers handle their infants' and children's emotional development differently from non-Latinx White mothers?
Lawren/Moment/Getty Images

their caregivers and whether children's caregivers are depressed or not (van der Asdonk, Cyr, & Alink, 2021). When infants become stressed, they show better biological recovery from the stressors when their caregivers engage in sensitive caregiving (Mitsven & others, 2021).

Cultural variations characterize emotional development (Suarez-Alvarez & others, 2020). For example, researchers have found that East Asian infants display less frequent and less intense positive and negative emotions than non-Latinx White infants (Cole & Tan, 2007). Throughout childhood, East Asian parents encourage their children to be emotionally reserved rather than emotionally expressive (Cole, 2016). Further, Japanese parents try to prevent children from experiencing negative emotions, whereas non-Latinx White mothers more frequently respond after their children become distressed and then try to help them cope (Rothbaum & Trommsdorff, 2007).

EMOTION REGULATION

Too often when people think about emotion they think about it in negative ways, such as having emotional problems. However, emotion can be adaptive and help individuals live more competent, enriching lives. In terms of emotions being adaptive, consider that infants communicate via emotion even before they understand language and their emotions are critical to their survival and thus their adaptation. As we see next, emotion regulation plays a key role in the adaptiveness of emotions, especially ensuring that emotional arousal does not interfere with our daily functioning and relationships (Beckes & Edwards, 2020).

The ability to control how we express our emotions is a key dimension of development (Mitsven & others, 2021). Emotion regulation consists of effectively managing arousal to adapt to circumstances and to reach a goal. Arousal involves a state of alertness or activation, which can reach levels that are too high for effective functioning. Anger, for example, often requires regulation.

In infancy and early childhood, regulation of emotion gradually shifts from external sources to self-initiated, internal sources. Also, with increasing age, children tend to improve their use of cognitive strategies for regulating emotion, to modulate their emotional arousal, to become more adept at managing situations to minimize negative emotion, and to choose effective ways to cope with stress (Bell & Broomell, 2021).

Emotion regulation is involved in many aspects of children's and adolescents' development, and there are wide variations in children's and adolescents' ability to modulate their emotions (Norona-Zhou & Tung, 2021). Indeed, a prominent feature of children and adolescents who have problems is that they often have difficulty managing their emotions (Desatnik & others, 2021). Ineffective emotion regulation is linked with a lower level of executive function, difficulty succeeding in school, a lower level of moral development (weak conscience and lack of internalization of rules, for example), failure to adequately cope with stress, and difficulty in peer relations (Cole, Ram, & English, 2019; Xie, Liu, & Fang, 2021). A recent research review concluded that emotion regulation at 3 to 5 years of age plays an important role in young children's school readiness in both socioemotional and academic domains (Harrington & others, 2020). In sum, many researchers consider the growth of emotion regulation in children as a fundamental aspect of the development of social competence (Thompson & Waters, 2020).

Parents can play an important role in helping young children regulate their emotions (Altafim, McCoy, & Linhares, 2021; Perry & others, 2020). Depending on how they talk with their children about emotion, parents can be described as taking an *emotion-coaching* or an *emotion-dismissing* approach (Gottman, 2021). The distinction between these approaches is most evident in the way the parent deals with the child's negative emotions (anger, frustration, sadness, and so on) (England-Mason & Gonzalez, 2020). *Emotion-coaching parents* monitor their children's emotions, view their children's negative emotions as opportunities for teaching, assist them in labeling emotions, and coach them in how to deal effectively with emotions. In contrast, *emotion-dismissing parents* view their role as to deny, ignore, or change negative emotions. Researchers have observed that emotion-coaching parents interact with their children in a less rejecting manner, use more scaffolding and praise, and are more nurturant than are emotion-dismissing parents (Gottman & DeClaire, 1997). Moreover, the children of emotion-coaching parents are better at soothing themselves when they get upset, are more effective in regulating their negative affect, focus their attention better, and have fewer behavior problems than the children of emotion-dismissing parents (Katz & others, 2020). Further, mothers' emotion-dismissing parenting is linked to toddlers' lower emotional competence, while mothers' emotion-coaching parenting is associated with toddlers' higher emotional competence (Ornaghi & others, 2019). In a recent study of 3- to 4-year-olds, a higher degree of paternal emotion

coaching predicted children's positive expression of emotion one year later (Gerhardt & others, 2020). And in a recent Chinese study, a Tuning in to Kids program that emphasizes emotion coaching was effective in improving the emotion coaching and decreasing the emotion dismissing of mothers of preschool children (Qiu & Shum, 2021).

A challenge parents face is that young children typically don't want to talk about difficult emotional topics, such as being distressed or engaging in negative behaviors. Among the strategies young children use to avoid these conversations are remaining silent, changing the topic, pushing the parent away, or running away. Young children are more likely to openly discuss difficult emotional circumstances when they are securely attached to their mothers.

Recently, Tracy Spinrad, Amanda Morris, and Sonja Luthar (2020) summarized a number of supportive and unsupportive caregiver emotion socialization strategies based on research across the last two decades:

An emotion-coaching parent. *What are some differences between emotion-coaching and emotion-dismissing parents?*
shironosov/Getty Images

Supportive Caregiver Emotion Socialization Strategies In most instances, caregivers should engage in:

- Having a positive emotional demeanor and mood when interacting with children
- Validating a children's emotions (although a child's behavior may be problematic, his or her emotions are not)
- Helping children learn to use emotion strategies that make them feel better or figure out how to solve the problem that produced the emotional distress
- Discussing emotions with children in a way that includes labeling emotions accurately and understanding the contexts and causes of emotion

Unsupportive Caregiver Emotion Socialization Strategies In most cases, caregivers should not engage in:

- Expressing uncontrolled or excessive negativity, such as becoming very irritated or displaying strong anger and hostility toward children
- Punishing children for emotions and feelings
- Dismissing or ignoring a child's expressions of emotion

EMOTIONAL COMPETENCE

In the "Intelligence" chapter, we briefly considered the concept of emotional intelligence. Here we examine a closely related concept, emotional competence, which focuses on the adaptive nature of emotional experience (Denham & Bassett, 2019). Carolyn Saarni (1999; Saarni & others, 2006) notes that becoming emotionally competent involves developing a number of skills in social contexts, including the following:

Skill	Example
Having awareness of one's emotional states	Being able to differentiate whether one feels sad or anxious
Detecting others' emotions	Understanding when another person is sad rather than afraid
Using the vocabulary of emotion terms in socially and culturally appropriate ways	Appropriately describing a social situation in one's culture when a person is feeling distressed
Having empathetic and sympathetic sensitivity to others' emotional experiences	Being sensitive to other people when they are feeling distressed
Recognizing that inner emotional states do not have to correspond to outer expressions	Recognizing that one can feel very angry yet manage one's emotional expression so that it appears more neutral
Adaptively coping with negative emotions by using self-regulatory strategies that reduce the intensity or duration of such emotional states	Reducing anger by walking away from an aversive situation and engaging in an activity that takes one's mind off the aversive situation

developmental **connection**
Emotional Intelligence
Emotional intelligence involves perceiving and expressing emotions accurately, understanding emotion, having emotional knowledge, using feelings to facilitate thought, and managing emotions effectively. Connect to "Intelligence."

- *Having awareness that the expression of emotions plays a major role in relationships*
- *Viewing oneself overall as feeling the way one wants to feel*
- Knowing that expressing anger toward a friend on a regular basis is likely to harm the friendship
- Striving to cope effectively with the stress in one's life and feeling that one is doing this successfully

As children acquire these emotional competence skills in a variety of contexts, they are more likely to effectively manage their emotions, become resilient in the face of stressful circumstances, and develop more positive relationships (Denham & Bassett, 2019).

Does an adult's emotional life differ from an adolescent's? Does a young child's emotional life differ from an infant's? Does an infant even have an emotional life? In this section, we trace the changes in emotion over the life span, looking not only at changes in emotional experience but also at the development of emotional competence.

INFANCY

What are some early developmental changes in emotions? What functions do infants' cries serve? When do infants begin to smile?

Early Emotions A leading expert on infant emotional development, Michael Lewis (2007, 2015, 2018) distinguishes between primary emotions and self-conscious emotions. **Primary emotions** are emotions that are present in humans and other animals; these emotions appear in the first six months of the human infant's development. Primary emotions include surprise, interest, joy, anger, sadness, fear, and disgust (see Figure 1 for infants' facial expressions of some of these early emotions). In Lewis' classification, **self-conscious emotions** require self-awareness that involves consciousness and a sense of "me." Self-conscious emotions include jealousy, empathy, embarrassment, pride, shame, and guilt—with most of these emotions occurring for the first time after 18 months of age, when a sense of self becomes consolidated in toddlers.

Researchers such as Joseph Campos (2005) and Michael Lewis (2018) debate about how early in the infant and toddler years these self-conscious emotions first appear and what their sequence is. As an indication of the controversy regarding when certain emotions first are displayed by infants, consider jealousy.

Some researchers argue that jealousy does not emerge until infants are approximately 18 months old (Lewis, 2007), while others assert that it is displayed much earlier (Hart, 2018). Some research studies suggest that the appearance of jealousy might occur as early as 6 months of age (Hart & others, 2004). In one study, 6-month-old infants observed their mothers giving attention either to a lifelike baby doll (hugging or gently rocking it, for example) or to a book. When mothers directed their attention to the doll, the infants were more likely to display negative emotions, such as anger and sadness, which may have indicated their jealousy (Hart & Carrington, 2002) (see Figure 2). Some observers have been skeptical of this interpretation, suggesting that these infants' expressions of anger and sadness simply may have reflected frustration about not being able to have the novel doll to play with. However, in one study, 9-month-old infants displayed jealousy-related behavior and EEG patterns characteristic of jealousy when their mothers gave attention to a social rival (Mize & others, 2014).

Debate about the onset of an emotion such as jealousy illustrates the complexity and difficulty of indexing early emotions. That said, some experts on infant socioemotional development, such as Jerome Kagan (2013), conclude that the structural immaturity of the infant brain makes it unlikely that emotions requiring thought–such as guilt, pride, despair, shame, empathy, and jealousy–can be experienced during the first year. Nonetheless, some leading researchers have argued that research now indicates that empathy can be expressed before the infant's first birthday (Davidov & others, 2013).

FIGURE **2**

IS THIS THE EARLY EXPRESSION OF JEALOUSY? In the study by Hart and Carrington (2002), the researchers concluded that the reactions of 6-month-old infants who observed their mothers giving attention to a baby doll may indicate the early appearance of jealousy because of the negative emotions—such as anger and sadness—they displayed. However, experts on emotional development, such as Joseph Campos (2009) and Jerome Kagan (2010), argue that emotions such as jealousy don't appear during the first year. *Why do they conclude that jealousy does not occur in the first year?*
Kenny Braun/Braun Photography

Emotional Expression and Social Relationships Emotional expression is involved in infants' first relationships. Infants' ability to communicate emotions permits coordinated interactions with their caregivers and the beginning of an emotional bond between them (Walle & Lopez, 2020). Not only do parents change their emotional expressions in response to infants' emotional expressions, but infants also modify their emotional expressions in response to their parents' emotional expressions (Ogren & Johnson, 2021). In other words, these interactions are mutually regulated (Ribeiro-Accioly & others, 2019). Because of this coordination, the interactions are described as reciprocal, or synchronous, when all is going well. Sensitive, responsive parents help their infants grow emotionally, whether the infants respond in distressed or happy ways (Henderson, Burrows, & Usher, 2020). One study found that a higher level of maternal positive emotionality predicted more initial infant smiling and laughter, while a higher level of parental stress predicted less infant smiling and laughter (Bridgett & others, 2013). Also, a recent observational study of mother-infant interaction found that maternal sensitivity was linked to a lower level of infant fear (Gartstein, Hancock, & Iverson, 2018). And another study revealed that parents' elicitation of talk about emotion with toddlers was associated with the toddlers' sharing and helping behaviors (Brownell & others, 2013).

What are some different types of cries?
Andy Cox/The Image Bank/Getty Images

Cries and smiles are two emotional expressions that infants display when interacting with parents. These are babies' first forms of emotional communication.

Crying Crying is the most important mechanism newborns have for communicating with their world. The first cry verifies that the baby's lungs have filled with air. Cries also may provide information about the health of the newborn's central nervous system. How much do infants cry? In a recent study, a digital recording device was used to assess newborn daily crying time duration (Cabana & others, 2021). In this study of healthy, full-term newborns, during the first week of life the mean crying time was about 25 minutes per day, which then remained stable for several weeks, followed by an increase to almost 40 minutes per day at five weeks of age. Prior research on infant crying time was mainly based on parental reporting and suggested that infants cry less than this.

primary emotions Emotions that are present in humans and other animals, emerge early in life, and are culturally universal; examples are joy, anger, sadness, fear, and disgust.

self-conscious emotions Emotions that require consciousness and a sense of "me"; they include empathy, jealousy, embarrassment, pride, shame, and guilt, most of which first appear at some point after 18 months of age when a sense of self becomes consolidated in toddlers.

There is much concern about excessive infant crying. A recent study found that excessive crying in 3-month-olds doubled the risk of behavioral, hyperactive, and mood problems at 5 to 6 years of age (Smarius & others, 2017).

Babies have at least three types of cries:

- **Basic cry.** A rhythmic pattern that usually consists of a cry, followed by a briefer silence, then a shorter inspiratory whistle that is somewhat higher in pitch than the main cry, then another brief rest before the next cry. Some infancy experts stress that hunger is one of the conditions that incite the basic cry.
- **Anger cry.** A variation of the basic cry in which more excess air is forced through the vocal cords. The anger cry has a loud, harsh sound to it, almost like shouting.
- **Pain cry.** A sudden long, initial loud cry followed by breath holding; no preliminary moaning is present. The pain cry is stimulated by a high-intensity stimulus.

Most adults can determine whether an infant's cries signify anger or pain (Zeskind, 2007). Parents can distinguish between the various cries of their own baby better than those of another baby.

He who binds to himself a joy
Does the winged life destroy;
But he who kisses the joy as
it flies
Lives in eternity's sun rise.

—William Blake
English Poet, 19th Century

Smiling Smiling is critical as a means of developing a new social skill and is a key social signal (Martin & Messinger, 2018). Two types of smiling can be distinguished in infants:

- **Reflexive smile.** A smile that does not occur in response to external stimuli and appears during the first month after birth, usually during sleep.
- **Social smile.** A smile that occurs in response to an external stimulus, typically a face in the case of the young infant. Social smiling occurs as early as 4 to 6 weeks of age in response to a caregiver's voice (Messinger, 2008).

The infant's social smile can have a powerful impact on caregivers. Following weeks of endless demands, fatigue, and little reinforcement, their infant starts smiling at them and all of the caregivers' efforts are rewarded. Social smiling has also been linked to social and intellectual development. In one study, researchers found that smiling and laughter at 7 months of age were associated with self-regulation at 7 years of age (Posner & others, 2014). Also, in a longitudinal study, positive affect, but not negative affect, at 1.5 years of age predicted higher childhood IQ (at 6 to 8 years of age) and higher educational attainment in adulthood (at 29 years of age) (Coffey, 2020).

basic cry A rhythmic pattern usually consisting of a cry, a briefer silence, a shorter inspiratory whistle that is higher pitched than the main cry, and then a brief rest before the next cry.

anger cry A cry similar to the basic cry but with more excess air forced through the vocal cords.

pain cry A sudden, initial loud cry followed by breath holding, without preliminary moaning.

reflexive smile A smile that does not occur in response to external stimuli. It happens during the month after birth, usually during sleep.

social smile A smile in response to an external stimulus, which, early in development, typically is a face.

stranger anxiety An infant's fear of and wariness toward strangers; it tends to appear in the second half of the first year of life.

separation protest Reaction that occurs when infants experience a fear of being separated from a caregiver, which results in crying when the caregiver leaves.

Fear One of a baby's earliest emotions is fear. Recent research indicated that when infants were assessed at 6, 8, 10, and 12 months, fear peaked at 10 months (Gartstein, Hancock, & Iverson, 2018). Fear typically first appears at about 6 months of age, but abused and neglected infants can show fear as early as 3 months (Witherington & others, 2010).

The most frequent expression of an infant's fear involves **stranger anxiety,** in which an infant shows a fear and wariness of strangers (Brand, Escobar, & Patrick, 2020). Stranger anxiety usually emerges gradually. It first appears at about 6 months of age in the form of wary reactions. By age 9 months, the fear of strangers is often more intense, reaching a peak toward the end of the first year of life (Scher & Harel, 2008).

Not all infants show distress when they encounter a stranger. Besides individual variations, whether an infant shows stranger anxiety also depends on the social context and the characteristics of the stranger (Kagan, 2008).

Infants show less stranger anxiety when they are in familiar settings. It appears that when infants feel secure, they are less likely to show stranger anxiety.

In addition to stranger anxiety, infants experience fear of being separated from their caregivers. The result is **separation protest**—crying when the caregiver leaves. Separation protest is initially displayed by infants at approximately 7 to 8 months and peaks at about 15 months (Kagan, 2008). One study revealed that separation protest peaked at about 13 to 15 months in four different cultures (Kagan, Kearsley, & Zelazo, 1978). Although the percentage of infants who engaged in separation protest varied across cultures, the infants reached a peak of protest at about the same age—early in the second year of life.

Emotion Regulation and Coping Earlier, we discussed some general developmental changes in emotion regulation across the childhood years. Here we examine in detail how infants develop emotion regulation and coping skills.

During the first year of life, the infant gradually develops an ability to inhibit, or minimize, the intensity and duration of emotional reactions (Dollar & Calkins, 2020). From early in infancy, babies put their thumbs in their mouths to soothe themselves. But at first, infants mainly depend on caregivers to help them soothe their emotions, as when a caregiver rocks an infant to sleep, sings lullabies to the infant, gently strokes the infant, and so on. In one study, researchers found that young infants with a negative temperament used fewer attention regulation strategies than infants with a positive temperament, and maternal sensitivity to infants was linked to more adaptive emotion regulation (Thomas & others, 2017). Another study also linked maternal sensitivity to better emotion regulation in 10-month-old infants (Frick & others, 2018).

Later in infancy, when they become emotionally aroused, infants sometimes redirect their attention or distract themselves in order to reduce their arousal. By 2 years of age, toddlers can use language to define their feeling states and the context that is upsetting them (Kopp, 2008). A toddler might say, "Feel bad. Dog scare." This type of communication may allow caregivers to help the child learn how to regulate emotion.

Contexts can influence emotion regulation (Geyer & Ogbonnaya, 2021; Godleski & others, 2020). Infants are often affected by fatigue, hunger, time of day, the people who are around them, and where they are. Infants must learn to adapt to different contexts that require emotion regulation. Further, new demands appear as the infant becomes older and parents modify their expectations (Mitsven & others, 2021). For example, parents may take it in stride if their 6-month-old infant screams in a grocery store but may react very differently if their 2-year-old starts screaming.

To soothe or not to soothe—should a crying baby be given attention and soothed, or does this attention spoil the infant? Many years ago, behaviorist John Watson (1928) argued that parents spend too much time responding to infant crying. As a consequence, he said, parents reward crying and increase its incidence. Some researchers have found that a caregiver's quick, soothing response to crying increased crying (Gewirtz, 1977). However, infancy experts Mary Ainsworth (1979) and John Bowlby (1989) argue that a quick, comforting response to an infant's cries is an important ingredient in the development of a strong bond between the infant and caregiver. In one of Ainsworth's studies, infants whose mothers responded quickly when they cried at 3 months of age cried less later in the first year of life (Bell & Ainsworth, 1972).

Should a crying baby be given attention and soothed, or does this spoil the infant? Should the infant's age, the type of cry, and the circumstances be considered?
Photodisc Collection/Getty Images

Controversy continues to surround the question of whether or how parents should respond to an infant's cries. Some developmentalists argue that an infant cannot be spoiled in the first year of life, a view suggesting that parents should soothe a crying infant. In one study a group of mothers received training in effective soothing techniques during the fourth week after birth, and assessments conducted 7, 11, and 23 weeks after birth found that the infants in the experimental group woke up less at night and cried less than did infants in the control group (Ozturk Donmez & Bayik Temel, 2019). However, a recent study also found that when parents "let their infants cry it out" in the first six months, this practice was not associated with adverse behavioral development and attachment at 18 months (Bilgin & Wolke, 2020). In another recent study, infants who were left to "cry it out" showed highly problematic behavior at 3 months of age but lower rates of problematic behavior at 12 months (Giesbrecht & others, 2020). In sum, there are somewhat mixed results about whether infants' development is harmed when parents do not respond immediately to their cries, such as in middle-of-the-night crying. That said, when parents perceive that their infant's cry is a response to pain or fear, they should always respond immediately in a nurturing manner.

EARLY CHILDHOOD

The young child's growing awareness of self is linked to the ability to feel an expanding range of emotions. Young children, like adults, experience many emotions during the course of a day. At times, they also try to make sense of other people's emotional reactions and to control their own emotions (Frydenberg, Deans, & Liang, 2020).

Expressing Emotions Recall from our earlier discussion that even young infants experience emotions such as joy and fear, but to experience self-conscious emotions, children must be able to refer to themselves and be aware of themselves as distinct from others (Lewis, 2020). Pride, shame, embarrassment, and guilt are examples of self-conscious emotions. Self-conscious

James Woodson/Digital Vision/Getty Images

emotions do not appear to develop until self-awareness appears during the second half of the second year of life.

During early childhood, emotions such as pride and guilt become more common (Lewis, 2020). They are especially influenced by parents' responses to children's behavior (Thompson, 2015). For example, a young child may experience shame when a parent says, "You should feel bad about biting your sister."

Understanding Emotions Among the most important changes in emotional development in early childhood is an increased understanding of emotion (Hare & others, 2021). During early childhood, young children increasingly understand that certain situations are likely to evoke particular emotions, facial expressions indicate specific emotions, emotions affect behavior, and emotions can be used to influence others' emotions (Cole & others, 2009). In one study, young children's emotional understanding was linked to how extensively they engaged in prosocial behavior (Ensor, Spencer, & Hughes, 2010). In a recent study of young children, a lower level of maternal depression and a higher level of children's executive control predicted a higher level of children's emotion knowledge (Thompson & others, 2020).

Between 2 and 4 years of age, children use an increasing number of terms to describe emotions. During this time, they are also learning about the causes and consequences of feelings.

When they are 4 to 5 years of age, children show an increased ability to reflect on emotions. They also begin to understand that the same event can elicit different feelings in different people. Moreover, they show a growing awareness that they need to manage their emotions to meet social standards (Denham & Zinsser, 2015). And, by 5 years of age, most children can accurately identify emotions that are produced by challenging circumstances and describe strategies they might call on to cope with everyday stress (Cole & others, 2009).

Regulating Emotions Many researchers consider the growth of emotion regulation in children as fundamental to the development of social competence (Dollar & Calkins, 2020). For example, in a recent study, children's emotion regulation expressed in being able to manage feelings of sadness and worry served as a buffer against internalizing symptoms associated with peer victimization (Cooley & others, 2021).

Emotion regulation can be conceptualized as an important component of self-regulation or of executive function (Bell & Broomell, 2021). Executive function is increasingly thought to be a key concept in describing the young child's higher-level cognitive functioning (Riccio & Castro, 2021). Cybele Raver and her colleagues (Raver & others, 2011, 2012, 2013, 2016) are using various interventions, such as increasing caregiver emotional expressiveness, to improve young children's emotion regulation and reduce behavior problems in children growing up in poverty.

Emotions also play a strong role in determining the success of a child's peer relationships (Ettekal & Ladd, 2020; Herd & Kim-Spoon, 2021). Specifically, the ability to modulate one's emotions is an important skill that benefits children in their relationships with peers. Moody and emotionally negative children are more likely to experience rejection by their peers, whereas emotionally positive children are more popular. One study found that young children with higher emotion regulation were more popular with their peers (Nakamichi, 2017). Also, in another recent study of preschool children, frequent expression of anger predicted lower social competence in peer relations one year later (Lindsey, 2019).

MIDDLE AND LATE CHILDHOOD

During middle and late childhood, many children show marked improvement in understanding and managing their emotions. However, in some instances, such as when they experience stressful circumstances, their coping abilities may be challenged (Denham & Bassett, 2019). In one study, a low level of emotion regulation in childhood was especially important in predicting a higher level of externalizing problems in adolescence (Perry & others, 2018). In another study, better emotion regulation at 10 years of age was linked to earlier maternal support of emotional development at 5 years of age and also predicted better adolescent adjustment at 15 years of age (Perry & others, 2020). Also, in recent research, girls had higher

emotion regulation at 9 to 12 years of age than at 13 to 16 years of age, while the reverse occurred for boys (Sanchis-Sanchis & others, 2020).

Developmental Changes in Emotion Middle and late childhood brings significant progress in emotional development, including the following changes (Cole, Ram, & English, 2019; Denham, Bassett, & Wyatt, 2015; Kuebli, 1994; Perry & Calkins, 2018):

- *Improved emotional understanding*. Children in elementary school develop an increased ability to understand complex emotions such as pride and shame. These emotions become less tied to the reactions of other people; instead, they are more self-generated and integrated with a sense of personal responsibility. A child may feel a sense of pride about developing new reading skills or shame after hurting a friend's feelings. Also, during middle and late childhood as part of their understanding of emotions, children can engage in "mental time travel," in which they anticipate and recall the cognitive and emotional aspects of events (Hjortsvang & Lagattuta, 2017; Kramer & Lagattuta, 2018, 2021; Lagattuta, 2014a, b).
- *Marked improvements in the ability to suppress or conceal negative emotional reactions*. During this period, children sometimes intentionally hide their emotions. Although a boy may feel sad or angry because a friend does not want to play with him, for example, he may decide not to share those feelings with his parents.
- *The use of self-initiated strategies for redirecting feelings*. In the elementary school years, children reflect more about emotional experiences and develop strategies to cope with their emotional lives. Children can more effectively manage their emotions by cognitive means, such as using distracting thoughts. A boy may be excited about his birthday party that will take place later in the afternoon, but still be able to concentrate on his schoolwork during the day.
- *An increased tendency to take into fuller account the events leading to emotional reactions*. A fourth-grader may become aware that her sadness today is influenced by her friend's moving to another town last week.
- *Development of a capacity for genuine empathy*. Two girls might see another child in distress on the playground and run to the child and ask if they can help.

Social-Emotional Education Programs An increasing number of social-emotional education programs have been developed to improve many aspects of children's and adolescents' lives (DiPerna, Frey, & Hart, 2021; England-Mason & Gonzalez, 2020). Two such programs are the Second Step program created by the Committee for Children (2021) and the social and emotional learning (SEL) programs created by the Collaborative for Academic, Social, and Emotional Learning (CASEL, 2021). Many social-emotional education programs only target young children, but Second Step can be implemented in pre-K through eighth grade and SEL can used with pre-K through twelfth-grade students.

Second Step focuses on the following aspects of social-emotional learning from pre-K through the eighth grade: (1) pre-K: self-regulation and executive function skills that improve attention and help children control their behavior; (2) kindergarten through grade 5: making friends, engaging in self-regulation of emotion, and solving problems; and (3) grades 6 through 8: communication skills, coping with stress, and decision making to avoid engaging in problem behaviors.

SEL programs target five core social and emotional learning domains: (1) self-awareness (recognizing one's emotions and how they affect behavior, for example); (2) self-management (self-control, coping with stress, and impulse control, for example); (3) social awareness (perspective taking and empathy, for example); (4) relationship skills (developing positive relationships and communicating effectively with individuals from diverse backgrounds, for example); and (5) responsible decision making (engaging in ethical behavior and understanding the consequences of one's actions, for example).

Coping with Stress An important aspect of children's lives is learning how to cope with stress (Fisher & others, 2021). As children get older, they are able to more accurately appraise a stressful situation and determine how much control they have over it. Older children

generate more alternatives for coping with stressful conditions and make greater use of cognitive coping strategies (Saarni & others, 2006). For example, older children are better than younger children at intentionally shifting their thoughts to a topic that is less stressful. Older children are also better at reframing, or changing their perception of a stressful situation. For example, younger children may be very disappointed that their teacher did not say hello to them when they arrived at school. Older children may reframe this type of situation and think, "She may have been busy with other things and just forgot to say hello."

By 10 years of age, most children are able to use cognitive strategies to cope with stress (Saarni & others, 2006). However, in families that have not been supportive and are characterized by turmoil or trauma, children may be so overwhelmed by stress that they do not use such strategies (Thabet & others, 2009).

Disasters can especially harm children's development and produce adjustment problems (Masten, 2021a, b; Masten & others, 2021). In 2020, the abrupt emergence of the worldwide spread of COVID-19 took people by surprise and increased the stress and anxiety levels of many adults and children. This pandemic caused a majority of schools to close and many adults to work from home. In such stressful circumstances, it is important for parents to stay calm, educate themselves about the virus, and communicate accurate information about the virus to their children. Especially important is that children understand that such viruses are not permanent and that eventually their lives will return to normal.

Among the outcomes for children who experience disasters such as a global pandemic, hurricane, or school shooting incident are acute stress reactions, depression, panic disorder, and post-traumatic stress disorder (Masten, 2021a ,b; Masten & others, 2021). The likelihood that a child will face these problems following a disaster depends on factors such as the nature and severity of the disaster and the type of support available to the child. In a recent meta-analysis of 15 studies and almost 23,000 children, anxiety, depression, irritability, boredom, inattention, and fear were the main new-onset psychological problems that emerged during the COVID-19 pandemic (Kumar Panda & others, 2021).

In research on disasters and trauma, the term *dose-response effects* is often used. A widely supported finding in this research area is that the more severe the disaster or trauma (dose), the worse the adaptation and adjustment (response) following the disaster or trauma (Narayan & Masten, 2019).

Children who have developed a number of coping techniques have the best chance of adapting and functioning competently in the face of disasters and traumas (Mash & Wolfe, 2019). Following are some recommendations for helping children cope with the stress of especially devastating events (Gurwitch & others, 2001, pp. 4–11):

- *Reassure children of their safety and security*. This step may need to be taken numerous times.
- *Allow children to retell events and be patient in listening to them*.
- *Encourage children to talk about any disturbing or confusing feelings*. Tell them that these are normal feelings after a stressful event.
- *Help children make sense of what happened*. Children may misunderstand what took place. For example, young children "may blame themselves, believe things happened that did not happen, believe that terrorists are in the school, etc. Gently help children develop a realistic understanding of the event" (p. 10).
- *Protect children from re-exposure to frightening situations and reminders of the trauma*. This strategy includes limiting conversations about the event in front of the children and limiting their exposure to media coverage of the event.

What are some effective strategies to help children cope with traumatic events such as the mass shooting at Sandy Hook Elementary School in Connecticut?
Stephanie Keith/Polaris/Newscom

Child and adolescent psychiatrists are among the mental health professionals who help youth cope with stress, including traumatic experiences. To read about a child psychiatrist who treats children and adolescents, see *Connecting with Careers.*

connecting with careers

Melissa Jackson, Child Psychiatrist

Dr. Melissa Jackson is a child and adolescent psychiatrist in Miami, Florida. She obtained a medical degree from the University of Florida and then completed an internship and residency in psychiatry at Advocate Lutheran General Hospital in Chicago, followed by a fellowship in child and adolescent psychiatry at the University of Southern California. Among the problems and disorders that Dr. Jackson treats are post-traumatic stress disorder (PTSD), attention deficit hyperactivity disorder (ADHD), anxiety, autism, depression, and a number of behavioral issues. In addition to her psychiatric treatment of children, she founded Health for Honduras, which includes trips to Honduras to provide services to children in orphanages.

To become a child and adolescent psychiatrist like Melissa Jackson, you would need to obtain an undergraduate degree, then earn a medical degree, then spend three to four years as a resident physician in general psychiatry, and then complete a two-year fellowship in the subspecialty of child and adolescent psychiatry. An important aspect of being a psychiatrist is that psychiatrists can prescribe medication, which psychologists cannot do.

To read further about child and adolescent psychiatrists, see the Careers Appendix at the end of the "Introduction" chapter.

ADOLESCENCE

Adolescence has long been described as a time of emotional turmoil (Hall, 1904). Adolescents are not constantly in a state of "storm and stress," but emotional highs and lows do increase during early adolescence (Rosenblum & Lewis, 2003; Somerville, 2018). Young adolescents can be on top of the world one moment and down in the dumps the next. In some instances, the intensity of their emotions seems out of proportion to the events that elicit them (Morris, Cui, & Steinberg, 2012). Young adolescents might sulk a lot, not knowing how to adequately express their feelings. With little or no provocation, they can blow up at their parents or siblings, a response that might reflect the defense mechanism of displacing their feelings onto another person. For some adolescents, such emotional swings can reflect serious problems.

Reed Larson and Maryse Richards (1994) found that adolescents reported more extreme emotions and more fleeting emotions than their parents did. For example, adolescents were five times more likely to report being "very happy" and three times more likely to report being "very unhappy" than their parents were (see Figure 3). These findings lend support to the perception of adolescents as moody and changeable (Rosenblum & Lewis, 2003).

Emotion Regulation Emotion regulation is involved in many aspects of adolescents' development, and there are wide variations in adolescents' ability to modulate their emotions (Cheung, Chan, & Chung, 2020; Zafar, Debowska, & Boduszek, 2021). Indeed, a prominent feature of adolescents with problems is that they often have difficulty managing their emotions. Ineffective emotion regulation is linked with a lower level of executive function, difficulty succeeding in school, a lower level of moral development (weak conscience and lack of internalization of rules, for example), failure to adequately cope with stress, and difficulty in peer relations (Cole, Ram, & English, 2019). In a recent study, higher levels of maternal and peer emotional support were linked to lower levels of adolescent girls' daily negative affect and also predicted increases in the girls' emotion regulation over time (Cui & others, 2020).

Depression Depression is more common in adolescence than in childhood, and it is becoming more prevalent among adolescents (Dietz, Silk, & Amole, 2019). Approximately 15 to 20 percent of adolescents experience major depressive disorder (Graber & Sontag, 2009). Adolescents who are experiencing a high level of stress and/or a loss of some type are at increased risk for developing depression (Endedijk & others, 2020). One study revealed that low self-esteem and negative emotion management in adolescence were linked to depression (Fiorilli & others, 2019). Further, a recent study revealed that interpersonal stress was linked to increased depression in adolescent girls (Slavich & others, 2020). And a recent research review concluded that adolescents often have difficulty recognizing

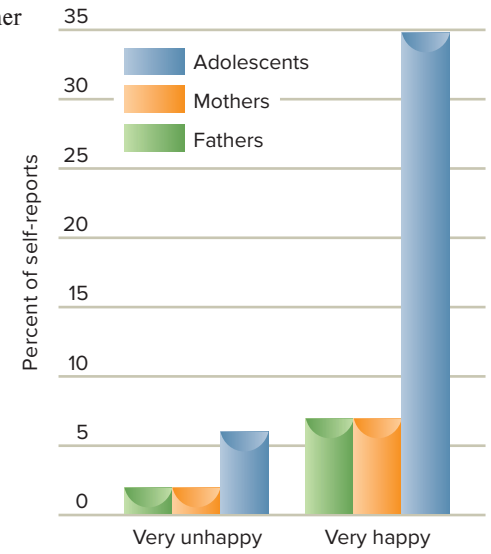

FIGURE 3

SELF-REPORTED EXTREMES OF EMOTION BY ADOLESCENTS, MOTHERS, AND FATHERS USING THE EXPERIENCE SAMPLING METHOD. In the study by Reed Larson and Maryse Richards (1994), adolescents and their mothers and fathers were beeped at random times by researchers using the experience sampling method. The researchers found that adolescents reported more emotional extremes than their parents did.

depression, seek help from informal rather than professional sources, and attach stigma to depression (Singh, Zaki, & Farid, 2019).

Is adolescent depression linked to adult problems? A longitudinal study found that a majority of adolescents who had a major depressive episode were likely to experience a recurrence of depression 15 years later (Alaie & others, 2019). In addition, adolescent depression was associated with other mental health problems, low educational attainment, and problems in intimate relationships when assessed 15 years later. It is, however, important to recognize that moodiness is a normal aspect of adolescence and to understand that most adolescents make it through these moody times to become competent adults.

ADULT DEVELOPMENT AND AGING

Like children, adults adapt more effectively when they are emotionally intelligent—when they are skilled at perceiving and expressing emotion, understanding emotion, using feelings to facilitate thought, and managing emotions effectively. (In the chapter on "Families, Lifestyles, and Parenting," we examine a number of aspects of relationships that involve emotions.)

Developmental changes in emotion continue through the adult years (Jarman & Windsor, 2021). The changes often are characterized by an effort to create lifestyles that are emotionally satisfying, predictable, and manageable by making decisions about an occupation, a life partner, and other circumstances. Of course, not all individuals are successful in these efforts. A key theme of emotional development in adulthood is "the adaptive integration of emotional experience into satisfying daily life and successful relationships with others" (Thompson & Goodvin, 2007, p. 402).

Stress and Gender Women and men differ in the way they experience and respond to stressors (Taylor, 2018, 2021). Women are more vulnerable to social stressors such as those involving romance, family, and work. For example, women experience higher levels of stress when things go wrong in romantic and marital relationships. Women also are more likely than men to become depressed when they encounter stressful life events such as a divorce or the death of a friend.

When men face stress, they are likely to respond in a **fight or flight** manner—become aggressive, withdraw from social contact, or drink alcohol. By contrast, according to Shelley Taylor (2018, 2021), when women experience stress, they are more likely to engage in a **tend and befriend** pattern, seeking social alliances with others, especially friends. Taylor argues that when women experience stress an influx of the hormone *oxytocin*, which is linked to nurturing in animals, is released.

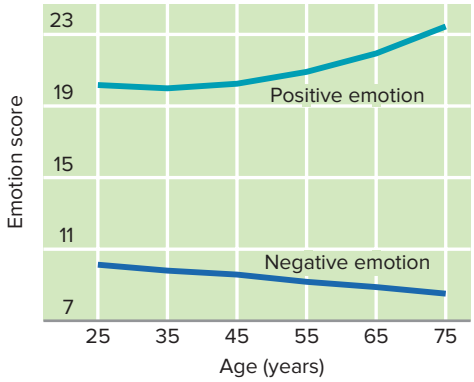

FIGURE **4**

CHANGES IN POSITIVE AND NEGATIVE EMOTION ACROSS THE ADULT YEARS. Positive and negative scores had a possible range of 6 to 30, with higher scores reflecting positive emotion and lower scores negative emotion. Positive emotion increased in middle and late adulthood, while negative emotion declined.

Positive and Negative Emotions Stereotypes suggest that older adults' emotional landscape is bleak and that most live sad, lonely lives. Researchers have found a different picture (Carstensen, 2019). One study of a very large U.S. sample examined emotions at different ages (Mroczek & Kolarz, 1998). Older adults reported experiencing more positive emotion and less negative emotion than younger adults, and positive emotion increased with age in adults at an accelerating rate (see Figure 4). In another study, emotional experiences of individuals 22 to 93 years of age were assessed in the mornings and evenings (English & Carstensen, 2014b). Older adults reported experiencing more positive emotions than younger adults at both times of the day. And in a recent study, older adults reacted with less anger about a personal memory than younger adults did (Kunzmann & others, 2017).

Overall, compared with younger adults, the feelings of older adults mellow (Carstensen, 2019). Emotional life is on a more even keel, with fewer highs and lows. It may be that although older adults have less extreme joy, they have more contentment, especially when they are connected in positive ways with friends and family. Compared with younger adults, older adults react less strongly to negative circumstances, are better at ignoring irrelevant negative information, and remember more positive than negative information (Carstensen & DeLiema, 2018). Research has also indicated that healthy older adults who age successfully show reduced responsiveness to regrets, not looking back with anger at missed opportunities in life (Brassen & others, 2012; Suri & Gross, 2012). Since opportunities to undo regrettable circumstances decrease with age, reduced connections with these situations

fight or flight Taylor's view that when men experience stress, they are more likely to become aggressive, withdraw from social contact, or drink alcohol.

tend and befriend Taylor's view that when women experience stress, they are more likely to seek social alliances with others, especially female friends.

may be a protective strategy to maintain well-being in old age. In a recent commentary, Laura Carstensen (2016) commented that when older adults focus on emotionally meaningful goals, they are more satisfied with their lives, feel better, and experience fewer negative emotions.

One study revealed that positive emotion increased and negative emotion (except for sadness) decreased from 50 years of age through the mid-eighties (Stone & others, 2010). In this study, a pronounced decline in anger occurred from the early twenties onward, and sadness was essentially unchanged from the early twenties through the mid-eighties. Another study found that aging was linked to more positive overall well-being and greater emotional stability (Carstensen & others, 2011). In this study, adults who experienced more positive than negative emotions were more likely to remain alive over a 13-year period. Other research also indicates that happier people live longer (Frey, 2011). Further, in a recent study, older men showed more engagement with highly positive contexts than did younger men (Martins & others, 2018). Also, in a recent meta-analysis of 72 studies of more than 19,000 individuals in 19 countries, it was concluded that emotional experiences are more positive in the lives of older adults than in the lives of younger adults (Laureiro-Martinez, Trujillo, & Unda, 2017). Also, in this review, it was concluded that older adults focus less on negative events in their past than younger adults do. And in a recent study of 18- to 76-year-olds during the COVID-19 pandemic, the age advantages in emotional experience persisted even during this prolonged highly stressful time (Carstensen, Shavit, & Barnes, 2020). In the study, older adults reported more positive and less negative emotion during the pandemic than younger participants. Thus, even in the face of persistent and dire threats to their health, older adults showed remarkable emotional resilience. In sum, research consistently documents that the emotional life of older adults is more positive than stereotypes suggest (Burr & others, 2021; Carstensen, 2019; Carstensen & DeLiema, 2018; Carstensen, Shavit, & Barnes, 2020; English & Carstensen, 2014b; Paul, 2019).

Recent research paints a distinctly positive picture of aging in the emotional domain.

—Laura Carstensen

Brain Development
The amygdala, where much of emotion is processed in the brain, matures by early adolescence, and the prefrontal cortex continues developing through emerging adulthood. Connect to "Physical Development and Biological Aging."

Socioemotional Selectivity Theory One theory developed by Laura Carstensen (1991, 1998, 2011, 2015, 2019) stands out as important in thinking about developmental changes in adulthood, especially in older adults. **Socioemotional selectivity theory** states that motivation changes as a function of time horizons. When time horizons are limited there is a shift in priorities that favor emotional meaning and satisfaction. Older adults become more selective about their social networks. Because they place a high value on emotional satisfaction, older adults often spend more time with familiar individuals with whom they have had rewarding relationships. This theory argues that older adults deliberately withdraw from social contact with individuals peripheral to their lives while they maintain or increase contact with close friends and family members with whom they have had enjoyable relationships. This selective narrowing of social interaction maximizes positive emotional experiences and minimizes emotional risks as individuals become older. According to this theory, older adults systematically condense their social networks so that available social partners satisfy their emotional needs (Sims, Hogan, & Carstensen, 2015). Also, the fact that older adults have a decreasing number of years to live likely influences them to place more emphasis on prioritizing meaningful relationships (Moss & Wilson, 2018). The priority placed on meaning is associated with greater selectivity about their social networks as they grow older.

Socioemotional selectivity theory challenges the stereotype that the smaller networks of older adults are related to emotional despair (Carstensen, 2016, 2019). Rather, carefully chosen and meaningful social networks lead them to spend more time than younger people engaged in emotionally rewarding moments with friends and family. Not surprisingly, older adults have far smaller social networks than younger adults do. In a study of individuals from 18 to 94 years of age, as they grew older they had fewer peripheral social contacts but retained close relationships with people who provided them with emotional support (English & Carstensen, 2014b).

Socioemotional selectivity theory also focuses on the types of goals that individuals are motivated to achieve (Carstensen, 2019). According to the theory, motivation for knowledge-related goals starts relatively high in the early years of life, peaks in adolescence and early adulthood, then declines in middle and late adulthood. The trajectory for emotion-related goals is high during infancy and early childhood, declines from middle childhood through early adulthood, and increases in middle and late adulthood.

3 Temperament

LG3 Characterize variations in temperament and their significance.

Describing and Classifying Temperament | Biological Foundations and Experience | Goodness of Fit and Parenting

Do you get upset a lot? Does it take much to get you angry or to make you laugh? Even at birth, babies seem to have different emotional styles. One infant is cheerful and happy much of the time; another baby seems to cry constantly. These tendencies reflect **temperament,** which involves individual differences in behavioral styles, emotions, and characteristic ways of responding. With regard to its link to emotion, temperament refers to individual differences in how quickly the emotion is shown, how strong it is, how long it lasts, and how soon it fades away (Campos, 2009).

Another way of describing temperament is in terms of predispositions toward emotional reactivity and self-regulation (Bates, McQuillan, & Hoyniak, 2019; Pozzi & others, 2021). *Reactivity* involves variations in the speed and intensity with which an individual responds to situations with positive or negative emotions. *Self-regulation* involves variations in the extent or effectiveness of an individual's control of emotions.

temperament An individual's behavioral style and characteristic way of responding.

easy child A temperament style in which the child is generally in a positive mood, quickly establishes regular routines, and adapts easily to new experiences.

difficult child A temperament style in which the child tends to react negatively and cry frequently, engages in irregular daily routines, and is slow to accept change.

slow-to-warm-up child A temperament style in which the child has a low activity level, is somewhat negative, and displays a low intensity of mood.

DESCRIBING AND CLASSIFYING TEMPERAMENT

How would you describe your temperament or the temperament of a friend? Researchers have described and classified the temperaments of individuals in different ways (Aktar & Perez-Edgar, 2021). Here we examine three of those ways.

Chess and Thomas' Classification Psychiatrists Alexander Chess and Stella Thomas (Chess & Thomas, 1977; Thomas & Chess, 1991) identified three basic types, or clusters, of temperament:

- An **easy child** is generally in a positive mood, quickly establishes regular routines in infancy, and adapts easily to new experiences.
- A **difficult child** reacts negatively and cries frequently, engages in irregular daily routines, and is slow to accept change.
- A **slow-to-warm-up child** has a low activity level, is somewhat negative, and displays a low intensity of mood.

In their longitudinal investigation, Chess and Thomas found that 40 percent of the children they studied could be classified as easy, 10 percent as difficult, and 15 percent as slow to warm up. Notice that 35 percent did not fit any of the three patterns. Researchers have found that these three basic clusters of temperament are moderately stable across the childhood years. In a recent study of low-income families, having a difficult temperament at 0 to 12 months of age predicted behavior problems at 36 months of age (Maltby & others, 2019).

What characterizes an inhibited temperament?
Jacqueline Veissid/Getty Images

Kagan's Behavioral Inhibition Another way of classifying temperament focuses on the differences between a shy, subdued, timid child and a sociable, extraverted, bold child (Callueng, Emam, & Oakland, 2020). Jerome Kagan (2002, 2010, 2019) regards shyness with strangers (peers or adults) as one feature of a broad temperament category called *inhibition to the unfamiliar*. Beginning at about 7 to 9 months, inhibited children react to many aspects of unfamiliarity with initial avoidance, distress, or subdued affect. In Kagan's research, inhibition shows some continuity from infancy through early childhood, although a substantial number of infants who are classified as inhibited become less so by 7 years of age. Research findings indicate that infants and young children who have an inhibited temperament are at risk for developing social anxiety disorder in adolescence and adulthood (Fox & others, 2021).

Rothbart and Bates' Classification New classifications of temperament continue to be forged (Rothbart, Posner, & Sheese, 2021). Mary Rothbart and John Bates (2006) argue that three broad dimensions best represent what researchers have found to characterize the structure of temperament: extraversion/surgency, negative affectivity, and effortful control (self-regulation):

- *Extraversion/surgency* includes approach, pleasure, activity, smiling, and laughter. Kagan's uninhibited children fit into this category.
- *Negative affectivity* includes fear, frustration, sadness, and discomfort (Rothbart, 2004). These children are easily distressed; they may fret and cry often. Kagan's inhibited children fit this category.
- *Effortful control* (self-regulation) includes attentional focusing and shifting, inhibitory control, and low-intensity pleasure (Rothbart, 2004). Infants who are high on effortful control show an ability to keep their arousal from getting too high and have strategies for soothing themselves. By contrast, children low on effortful control are often unable to control their arousal; they become easily agitated and intensely emotional. One study revealed that effortful control was a strong predictor of academic success skills, including school readiness, math skills, and reading skills, in kindergarten children from low-income families (Morris & others, 2014). And in two recent studies, a lower level of effortful control was linked to attention deficit hyperactivity disorder (ADHD) (Einziger & others 2018; Willoughby, Gottfredson, & Stifter, 2017).

The description of temperament categories so far reflects the development of normative capabilities of children, not individual differences in children. The development of these capabilities, such as effortful control, allows individual differences to emerge (Bates & Pettit, 2015). For example, although maturation of the brain's prefrontal lobes must occur for any child's attention to improve and the child to achieve effortful control, some children develop effortful control while others do not. And it is these individual differences in children that are at the heart of temperament (Bates, McQuillan, & Hoyniak, 2019).

BIOLOGICAL FOUNDATIONS AND EXPERIENCE

How does a child acquire a certain temperament? Kagan (2019) argues that children inherit a physiology that biases them to have a particular type of temperament. However, through experience they may learn to modify their temperament to some degree (Bates & Pettit, 2015). For example, children may inherit a physiology that biases them to be fearful and inhibited, but they learn to reduce these tendencies (van Wijk & others, 2019).

Biological Influences Physiological characteristics have been linked with different temperaments (Rothbart, Posner, & Sheese, 2021). In particular, an inhibited temperament is associated with a unique physiological pattern that includes high and stable heart rate, high level of the hormone cortisol, and high activity in the right frontal lobe of the brain (Kagan, 2019). This pattern may be tied to the excitability of the amygdala, a structure of the brain that plays an important role in fear and inhibition. The temperament dimension of negative emotionality is linked to stress reactivity, which involves brain functioning (especially the hypothalamic-pituitary-adrenal (HPA) axis and its link to higher levels of cortisol) (Rothbart, 2011). And the development of effortful control is linked to advances in the brain's frontal lobes (Bates, 2012a, b).

What is heredity's role in the biological foundations of temperament? Twin and adoption studies suggest that heredity has a moderate influence on differences in temperament within a group of people (van Wijk & others, 2019).

Too often the biological foundations of temperament are interpreted as meaning that temperament cannot develop or change. However, important self-regulatory dimensions of temperament such as adaptability, soothability, and persistence look very different in a 1-year-old and a 5-year-old (Easterbrooks & others, 2013). These temperament dimensions develop and change with the growth of the neurobiological foundations of self-regulation (Dollar & Calkins, 2019).

developmental **connection**

Nature and Nurture

Twin and adoption studies have been used to sort out hereditary and environmental influences on development. Connect to "Biological Beginnings."

Gender, Culture, and Temperament Gender may be an important factor shaping the environmental context that influences temperament (Jenzer & others, 2019). Parents might react differently to an infant's temperament depending on whether the baby is a boy or a girl. For example, in one study, mothers were more responsive to the crying of irritable girls than to the crying of irritable boys (Crockenberg, 1986).

Similarly, the caregiver's reaction to an infant's temperament may depend in part on culture (Matsumoto & Juang, 2020). For example, behavioral inhibition is more highly valued in China than in North America, and researchers have found that Chinese children are more inhibited than Canadian infants are (Chen, Fu, & Zhao, 2015). In one study, the cultural differences in temperament were linked to parents' attitudes and behaviors (Chen & others, 1998). Canadian mothers of inhibited 2-year-olds were less accepting of their infants' inhibited temperament, whereas Chinese mothers were more accepting.

What are some ways that developmentalists have classified infants' temperaments? Which classification makes the most sense to you, based on your observations of infants?

Tom Merton/Photodisc/Getty Images

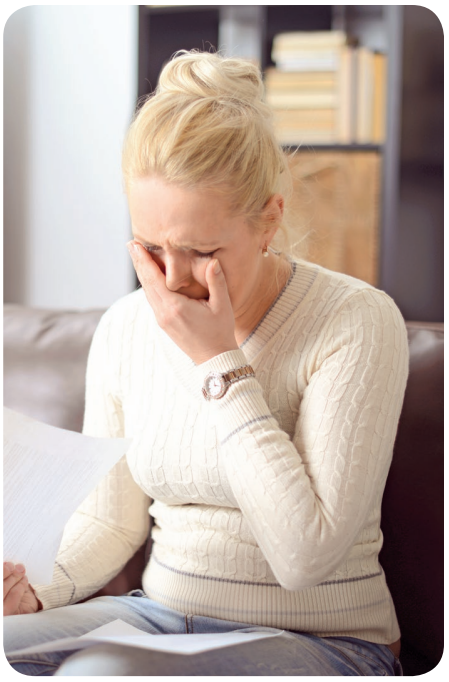
Developmental Connections in Temperament Is temperament in childhood linked with adjustment in adulthood? As described below, research has linked several of these types and dimensions during childhood with characteristics of adult personality (Shiner & DeYoung, 2013).

An infant's temperament can vary across cultures. *What do parents need to know about a child's temperament?*
Seiji Takemura/MIXA/Getty Images

- *Easy and difficult temperaments.* In one study, children who had an easy temperament at 3 to 5 years of age were likely to be well adjusted as young adults (Chess & Thomas, 1977). In contrast, many children who had a difficult temperament at 3 to 5 years of age were not well adjusted as young adults. Also, other researchers have found that boys with a difficult temperament in childhood are less likely as adults to continue their formal education, whereas girls with a difficult temperament in childhood are more likely to experience marital conflict as adults (Wachs, 2000). And a recent study revealed that a difficult temperament at 5 years of age was linked to delinquency at 15 years of age (DiLalla & DiLalla, 2018).
- *Inhibition.* Inhibition is another characteristic of temperament that has been studied extensively (Kagan, 2008, 2010, 2013). One study revealed that behavioral inhibition at 3 years of age was linked to shyness at age 7 (Volbrecht & Goldsmith, 2010). Also, research indicates that individuals with an inhibited temperament in childhood are less likely as adults to be assertive or to experience social support, and more likely to delay entering a stable job track (Asendorpf, 2008). Another study found that disinhibition in the toddler years was linked to career stability in middle adulthood (Blatny & others, 2015).

- *Ability to control one's emotions.* A recent study found that having an emotionally reactive temperament at 1 year of age was linked to having emotional problems at 5.5 years of age (Abulizi & others, 2017). Also, in a longitudinal study, when 3-year-old children showed good control of their emotions and were resilient in the face of stress, they were likely to continue to handle emotions effectively as adults (Block, 1993). By contrast, when 3-year-olds had low emotional control and were not very resilient, they were likely to show problems in these areas as young adults. Researchers have found that a high level of emotionality at 6 years of age is associated with depression in emerging adulthood (Bould & others, 2014).

How is temperament in childhood linked to socioemotional development in adulthood?
(*left*): Volodymyr Tverdokhlib/Shutterstock; (*right*): Elenaleonova/E+/Getty Images



In sum, these studies reveal some continuity between certain aspects of temperament in childhood and adjustment in early adulthood (Dagan & Sagi-Schwartz, 2021). However, keep in mind that these connections between childhood temperament and adult adjustment are based on only a small number of studies; more research is needed to verify these linkages.

GOODNESS OF FIT AND PARENTING

Goodness of fit refers to the match between a child's temperament and the environmental demands the child must cope with. Some temperament characteristics pose more parenting challenges than others, at least in modern Western societies (Dagan & Sagi-Schwartz, 2021). When children are prone to distress, as exhibited by frequent crying and irritability, their parents may eventually respond by ignoring the child's distress or trying to force the child to "behave." In one research study, though, extra support and training for mothers of distress-prone infants improved the quality of mother-infant interaction (van den Boom, 1989). Researchers also have found that decreases in infants' negative emotionality are linked to higher levels of parental sensitivity, involvement, and responsiveness (Gartstein, Hancock, & Iverson, 2018). Other findings support the use of positive parenting, including high warmth and low use of harsh control, to increase children's effortful control (Bates & Pettit, 2015).

To read further about some positive strategies for parenting that take into account the child's temperament, see the *Connecting Development to Life* interlude.

A final comment about temperament is that recently the *differential susceptibility model* and the *biological sensitivity to context model* have been proposed and studied (Belsky & van IJzendoorn, 2017; Zhang & others, 2021). According to these models, certain characteristics—such as a difficult temperament—that render children more vulnerable to difficulty in adverse contexts also make them more susceptible to optimal growth in very supportive conditions. Jay Belsky (2014) proposed the controversial view that intervention programs might try to target these children who are more vulnerable to difficulty in adverse conditions because of the greater cost-effectiveness involved in their being likely to flourish when given a lot of care and support. These models offer a new perspective on "negative" temperament characteristics.

goodness of fit The match between a child's temperament and the environmental demands the child must cope with.

connecting development to life

Parenting and the Child's Temperament

What are the implications of temperamental variations for parenting? Although answers to this question necessarily are speculative, the following conclusions regarding the best parenting strategies to use in relation to children's temperament were reached by temperament experts Ann Sanson and Mary Rothbart (1995):

- *Attention to and respect for individuality*. It is difficult to generate general prescriptions for "good" parenting. A goal might be accomplished in one way with one child and in another way with another child, depending on the child's temperament. Parents need to be sensitive and remain flexible to the infant's signals and needs.
- *Structuring the child's environment*. Crowded, noisy environments can pose greater problems for some children (such as a "difficult child") than others (such as an "easy" child). We might also expect that a fearful, inhibited child would benefit from slower entry into new contexts.
- *The "difficult child" and packaged parenting programs*. Programs for parents often focus on dealing with children who have "difficult" temperaments. In some cases, "difficult child" refers to Thomas and Chess' description of a child who reacts negatively, cries frequently, engages in irregular daily routines, and is slow to accept change. In others, the concept might be used to describe a child who is irritable, displays anger frequently, does not follow directions well, or shows some other negative characteristic. Acknowledging that some children are harder than others to parent is often helpful, and advice on how to handle specific difficult characteristics can be useful. However, whether a specific characteristic is difficult depends on its fit with the environment. To label a child "difficult" has the danger of becoming a self-fulfilling prophecy. If a child is identified as "difficult," people may treat the child in a way that actually elicits "difficult" behavior.

Too often, we pigeonhole children into categories without examining the context (Bates, McQuillan, & Hoyniak, 2019; Rothbart, Posner, & Sheese, 2021). Nonetheless, caregivers need to take children's temperaments into account. Research does not yet allow for many highly specific recommendations, but in general, caregivers should (1) be sensitive to the individual characteristics of the child, (2) be flexible in responding to these characteristics, and (3) avoid applying negative labels to the child.

What are some good strategies for parents to adopt when responding to their infant's temperament?

4 Attachment and Love

LG4 Explain attachment and its development.

Infancy and Childhood | Adolescence | Adulthood

So far, we have discussed how emotions and emotional competence change over the life span. We have also examined the role of emotional style—in effect, we have seen how emotions set the tone of our experiences in life. But emotions also write the lyrics because they are at the core of our relationships with others. Foremost among these relationships is **attachment,** a close emotional bond between two people. In this section, we focus on two types of attachment: the attachment between parents and children and the attachment between romantic partners.

INFANCY AND CHILDHOOD

Before describing parent-child attachment in detail, we will set the stage for its development by exploring the strength of social orientation among infants. We will also examine infants' early development of social cognition and its important role in infants' and young children's social behavior and interaction.

Social Orientation/Cognition In Ross Thompson's (2006, 2015, 2017, 2021) view, infants are socioemotional beings who show a strong interest in the social world and are motivated to orient to it and understand it. In other words, babies are socially smarter than used to be thought (Mitsven & others, 2021). In previous chapters, we described many of the biological and cognitive foundations that contribute to the infant's development of social orientation and cognition. Using techniques such as eye-tracking, violation of expectations, and habituation that were described in earlier chapters ("Motor, Sensory, and Perceptual Development" and "Cognitive Developmental Approaches"), researchers have discovered that infants have the capacity to understand others' actions and social interactions early in their development (Hamlin & Sitch, 2021). In this chapter we will call attention to relevant biological and cognitive factors as we explore social orientation; locomotion; intention, goal-directed behavior, and cooperation; and social referencing. Discussing biological, cognitive, and social processes together reminds us of an important aspect of development: these processes are intricately intertwined (Dollar & Calkins, 2019).

A mother and her baby engage in face-to-face play. *At what age does face-to-face play usually begin, and when does it typically start decreasing in frequency?*
Tom Grill/JGI/Blend Images/Getty Images

Social Orientation From early in their development, infants are captivated by their social world. Young infants will stare intently at faces and are attuned to the sounds of human voices, especially those of their caregivers (Durand & others, 2020). Later, they become adept at interpreting the meaning of facial expressions and voices (Paquette-Smith, Cooper, & Johnson, 2021).

Face-to-face play often begins to characterize caregiver-infant interactions when the infant is about 2 to 3 months of age. The focused social interaction of face-to-face play may include vocalizations, touch, and gestures. Such play results in part from many mothers' motivation to create a positive emotional state in their infants (Quinn & others, 2020).

In part because of such positive social interchanges between caregivers and infants, by 2 to 3 months of age infants respond differently to people and objects, showing more positive emotion to people than to inanimate objects such as puppets (Legerstee, 1997). At this age, most infants expect people to react positively when the infants initiate a behavior, such as a smile or a vocalization. The frequency of face-to-face play decreases after 7 months of age as infants become more mobile (Thompson, 2006). Infants also learn about the social world through contexts other than face-to-face play with a caregiver (Bornstein & Esposito, 2021). Even though infants as young as 6 months of age show an interest in each other, their interaction with peers increases considerably in the second half of the second year.

attachment A close emotional bond between two people.

social referencing "Reading" emotional cues in others to help determine how to act in a specific situation.

Locomotion Recall from earlier in the chapter how important independence is for infants, especially in the second year of life. As infants develop the ability to crawl, walk, and run, they are able to explore and expand their social world. These newly developed self-produced locomotor skills allow the infant to independently initiate social interchanges on a more frequent basis. The development of these gross motor skills is the result of a number of factors,

including the development of the nervous system, the goal the infant is motivated to reach, and environmental support for the skill (Adolph & Hoch, 2021).

The infant's and toddler's push for independence also is likely paced by the development of locomotor skills. Locomotion is also important for its motivational implications. Once infants have the ability to move in goal-directed pursuits, the reward from these pursuits leads to further efforts to explore and develop skills (Rachwani, Hoch, & Adolph, 2021).

Intention, Goal-Directed Behavior, and Cooperation Perceiving people as engaging in intentional and goal-directed behavior is an important social cognitive accomplishment that initially occurs toward the end of the first year (Thompson, 2015). Joint attention and gaze following help the infant to understand that other people have intentions (Piazza & others, 2020; Stout & others, 2021). *Joint attention* occurs when the caregiver and infant focus on the same object or event. By their first birthday, infants have begun to direct the caregiver's attention to objects that capture their interest (Marsh & Legerstee, 2017).

Amanda Woodward and her colleagues (Filippi & others, 2020; Krogh-Jespersen, Henderson, & Woodward, 2020; Krogh-Jespersen & Woodward, 2018) argue that infants' ability to understand and respond to others' meaningful intentions is a critical cognitive foundation for effectively engaging in the social world. They especially emphasize that an important aspect of this ability is the capacity to grasp social knowledge quickly in order to make an appropriate social response. Although processing speed is an important contributor to social engagement, other factors are involved, such as infants' motivation to interact with someone, the infant's social interactive history with the individual, the interactive partner's social membership, and culturally specific aspects of interaction (Krogh-Jesperson, Henderson, & Woodward, 2020).

Cooperating with others also is a key aspect of effectively engaging with others in the social world. Can infants engage in cooperation with others? One study involved presenting 1- and 2-year-olds with a simple cooperative task that consisted of pulling a lever to get an attractive toy (Brownell, Ramani, & Zerwas, 2006) (see Figure 5). Any coordinated actions of the 1-year-olds appeared to be more coincidental than cooperative, whereas the 2-year-olds' behavior was characterized as more actively cooperative efforts to reach a goal. In this study, the infants also were assessed with two social understanding tasks, observation of children's behavior in a joint attention task, and the parents' perceptions of the language the children use about the self and others (Brownell, Ramani, & Zerwas, 2006). Those with more advanced social understanding were more likely to cooperate. To cooperate, the children had to connect their own intentions with the peer's intentions and put this understanding to use in interacting with the peer to reach a goal.

Social Referencing Another important social cognitive accomplishment in infancy is developing the ability to "read" the emotions of other people (Carbajal-Valenzuela & others, 2017). **Social referencing** is the term used to describe "reading" emotional cues in others to help determine how to act in a specific situation. The development of social referencing helps infants to interpret ambiguous situations more accurately, as when they encounter a stranger and need to know whether or not to fear the person (Ehli & others, 2020). By the end of the first year, a mother's facial expression—either smiling or fearful—influences whether an infant will explore an unfamiliar environment.

Infants become better at social referencing in the second year of life. At this age, they tend to "check" with their mother before they act; they look at her to see if she is happy, angry, or fearful.

Infants' Social Sophistication and Insight In sum, researchers are discovering that infants are more socially sophisticated and insightful at younger ages than was previously envisioned (Thompson, 2017, 2021). Such sophistication and insight are reflected in infants' perceptions of others' actions as intentionally motivated and goal-directed, their motivation to share and participate in that intentionality, and their increase in emotional understanding and communication by their first birthday (Krogh-Jespersen, Henderson, & Woodward, 2020). These social cognitive skills could be expected to influence infants' understanding and awareness of attachment to a caregiver.

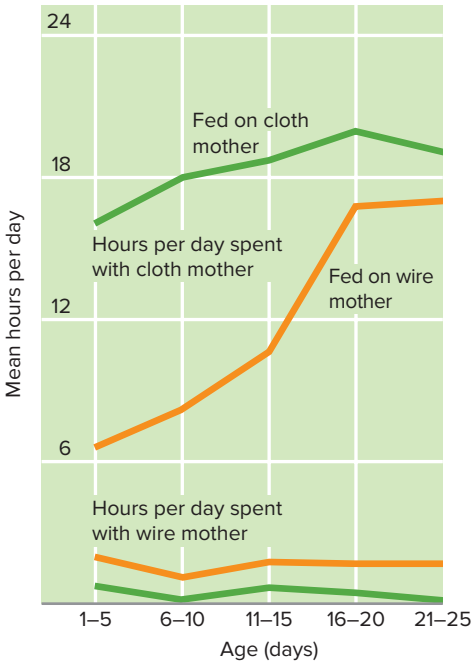
CONTACT TIME WITH WIRE AND CLOTH SURROGATE MOTHERS. Regardless of whether the infant monkeys were fed by a wire or a cloth mother, they overwhelmingly preferred to spend contact time with the cloth mother. *How do these results compare with what Freud's theory and Erikson's theory would predict about human infants?*

Martin Rogers/The Image Bank/Getty Images



What Is Attachment? There is no shortage of theories about why infants become attached to a caregiver. Three theorists—Freud, Erikson, and Bowlby—proposed influential views.

Freud noted that infants become attached to the person or object that provides oral satisfaction. For most infants, this is the mother, since she is most likely to feed the infant. Is feeding as important as Freud thought? A classic study by Harry Harlow (1958) reveals that the answer is no (see Figure 6).

Harlow removed infant monkeys from their mothers at birth; for six months they were reared by surrogate (substitute) "mothers." One surrogate mother was made of wire, the other of cloth. Half of the infant monkeys were fed by the wire mother, half by the cloth mother. Periodically, the amount of time the infant monkeys spent with either the wire or the cloth mother was computed. Regardless of which mother fed them, the infant monkeys spent far more time with the cloth mother. Even if the wire mother but not the cloth mother provided nourishment, the infant monkeys spent more time with the cloth mother. And when Harlow frightened the monkeys, those "raised" by the cloth mother ran to the mother and clung to it; those raised by the wire mother did not. Whether the mother provided comfort seemed to determine whether the monkeys associated the mother with security. This study clearly demonstrated that feeding is not the crucial element in the attachment process and that contact comfort is important.

Physical comfort also plays a role in Erik Erikson's (1968) view of the infant's development. Recall Erikson's proposal that the first year of life represents the stage of trust versus mistrust. Physical comfort and sensitive care, according to Erikson (1968), are key to establishing a basic trust in infants. The infant's sense of trust, in turn, is the foundation for attachment and sets the stage for a lifelong expectation that the world will be a good and pleasant place to be.

The ethological perspective of British psychiatrist John Bowlby (1969, 1989) also stresses the importance of attachment in the first year of life and the responsiveness of the caregiver. Bowlby stresses that both infants and their primary caregivers are biologically predisposed to form attachments. He argues that the newborn is biologically equipped to elicit attachment behavior. The baby cries, clings, coos, and smiles. Later, the infant crawls, walks, and follows the mother. The immediate result is to keep the primary caregiver nearby; the long-term effect is to increase the infant's chances of survival.

Attachment does not emerge suddenly but rather develops in a series of phases, moving from a baby's general preference for human beings to a partnership with primary caregivers. Following are four such phases based on Bowlby's conceptualization of attachment (Schaffer, 1996):

- *Phase 1: From birth to 2 months.* Infants instinctively direct their attachment to human figures. Strangers, siblings, and parents are equally likely to elicit smiling or crying from the infant.

- *Phase 2: From 2 to 7 months*. Attachment becomes focused on one figure, usually the primary caregiver, as the baby gradually learns to distinguish familiar from unfamiliar people.
- *Phase 3: From 7 to 24 months*. Specific attachments develop. With increased locomotor skills, babies actively seek contact with regular caregivers such as the mother or father.
- *Phase 4: From 24 months on*. Children become aware of others' feelings, goals, and plans and begin to take these into account in forming their own actions.

Researchers' recent findings that infants are more socially sophisticated and insightful than previously envisioned suggests that some of the characteristics of Bowlby's phase 4, such as understanding the goals and intentions of the attachment figure, appear to be developing in phase 3 as attachment security is taking shape.

Bowlby argued that infants develop an *internal working model* of attachment: a simple mental model of the caregiver, their relationship, and the self as deserving of nurturant care. The infant's internal working model of attachment with the caregiver influences the infant's and later, the child's, subsequent responses to other people (Thompson, 2021). The internal model of attachment also has played a pivotal role in the discovery of links between attachment and subsequent emotional understanding, conscience development, and self-concept (Dagan & Sagi-Schwartz, 2021). In sum, attachment emerges from the social cognitive advances that allow infants to develop expectations for the caregiver's behavior and to determine the affective quality of their relationship (Thompson, 2021). These social cognitive advances include recognizing the caregiver's face, voice, and other features, as well as developing an internal working model of expecting the caregiver to provide pleasure in social interaction and relief from distress.

In Bowlby's model, what are the four phases of attachment?
Camille Tokerud/Getty Images

Individual Differences in Attachment Although attachment to a caregiver intensifies midway through the first year, isn't it likely that the quality of babies' attachment experiences varies? Mary Ainsworth (1979) thought so. Ainsworth created the **Strange Situation,** an observational measure of infant attachment in which the infant experiences a series of introductions, separations, and reunions with the caregiver and an adult stranger in a prescribed order (Posada & others, 2021). In using the Strange Situation, researchers hope that their observations will provide information about the infant's motivation to be near the caregiver and the degree to which the caregiver's presence provides the infant with security and confidence (Brown & Cox, 2020; Watters & others, 2021).

Based on how babies respond in the Strange Situation, they are described as being securely attached or insecurely attached (in one of three ways) to the caregiver:

- **Securely attached children** use the caregiver as a secure base from which to explore the environment. When they are in the presence of their caregiver, securely attached infants explore the room and examine toys that have been placed in it. When the caregiver departs, securely attached infants might protest mildly, and when the caregiver returns these infants reestablish positive interaction with her, perhaps by smiling or climbing onto her lap. Subsequently, they usually resume playing with the toys in the room.
- **Insecure avoidant children** show insecurity by avoiding the mother. In the Strange Situation, these babies engage in little interaction with the caregiver, are not distressed when she leaves the room, usually do not reestablish contact with her on her return, and may even turn their back on her. If contact is established, the infant usually leans away or looks away.
- **Insecure resistant children** often cling to the caregiver and then resist her by fighting against the closeness, perhaps by kicking or pushing away. In the Strange Situation, these babies often cling anxiously to the caregiver and don't explore the playroom. When the caregiver leaves, they often cry loudly and push away if she tries to comfort them on her return, then want to be held again.
- **Insecure disorganized children** are disorganized and disoriented. In the Strange Situation, these babies might appear dazed, confused, and fearful. To be classified as disorganized, babies must show strong patterns of avoidance and resistance or display certain specified behaviors, such as extreme fearfulness around the caregiver.

Interpreting Differences in Attachment Do individual differences in attachment matter? Ainsworth notes that secure attachment in the first year of life provides an important

Strange Situation Ainsworth's observational measure of infant attachment to a caregiver that requires the infant to move through a series of introductions, separations, and reunions with the caregiver and an adult stranger in a prescribed order.

securely attached children Children who use the caregiver as a secure base from which to explore the environment.

insecure avoidant children Children who show insecurity by avoiding the mother.

insecure resistant children Children who might cling to the caregiver, then resist by fighting against the closeness, perhaps by kicking or pushing away.

insecure disorganized children Children who show insecurity by being disorganized and disoriented.

foundation for psychological development later in life. The securely attached infant moves freely away from the mother but keeps track of where she is through periodic glances. The securely attached infant responds positively to being picked up by others and, when put back down, freely moves away to play. An insecurely attached infant, by contrast, avoids the mother or is ambivalent toward her, fears strangers, and is upset by minor, everyday separations.

If early attachment to a caregiver is important, it should influence a child's social behavior later in development. For some children, early attachments seem to foreshadow later functioning (Dagan & Sagi-Schwartz, 2021; Thompson, Simpson, & Berlin, 2021a, b). In a recent study, Latinx infants were at higher risk for obesity if they showed avoidant or anxious insecure attachment behavior than if they showed secure attachment (Hepworth & others, 2021).

Some longitudinal studies indicate that infant attachment is linked to various outcomes in adolescence and adulthood. In the extensive longitudinal study conducted by Alan Sroufe (2016), early secure attachment (assessed by the Strange Situation at 12 and 18 months) was linked with positive emotional health, high self-esteem, self-confidence, and socially competent interaction with peers, teachers, camp counselors, and romantic partners through adolescence. Also, a longitudinal study found that infant attachment insecurity was linked to less effective emotion-regulation strategies (suppressing emotions, disengaging from close others, and exaggerating emotional expressions, for example) in relationship-challenging contexts 20 to 35 years later (Girme & others, 2021).

Few studies have assessed infants' attachment security to the mother and the father separately (Ahnert & Schoppe-Sullivan, 2020). However, one study revealed that infants who were insecurely attached to their mother and father ("double-insecure") at 15 months of age had more externalizing problems (out-of-control behavior, for example) during the elementary school years than their counterparts who were securely attached to at least one parent (Kochanska & Kim, 2013). Also, a recent study found that an infant's secure attachment to the father was not enough to reduce the infant's stress reactions when the mother-infant attachment was insecure (Kuo & others, 2019).

An important issue regarding attachment is whether infancy is a critical or sensitive period for development. Many, but not all, research studies reveal the power of infant attachment to predict subsequent development (Steele & Steele, 2019; Thompson, Simpson, & Berlin, 2021a, b; Waters & Roisman, 2018). In one longitudinal study, attachment classification in infancy did not predict attachment classification at 18 years of age (Lewis, Feiring, & Rosenthal, 2000). In this study, the best predictor of an insecure attachment classification at 18 was the occurrence of parental divorce in the intervening years.

Consistently positive caregiving over a number of years appears to be an important factor in connecting early attachment with the child's functioning later in development (Cowan & others, 2019a, b). Indeed, researchers have found that early secure attachment and subsequent experiences, especially maternal care and life stresses, are linked with children's later behavior and adjustment (Thompson, Simpson, & Berlin, 2021a, b). For example, a longitudinal study revealed that changes in attachment security or insecurity from infancy to adulthood were linked to stresses and supports in socioemotional contexts (Van Ryzin, Carlson, & Sroufe, 2011). These results suggest that attachment continuity may be a reflection of stable social contexts as much as early working models. The study just described (Van Ryzin, Carlson, & Sroufe, 2011) reflects an increasingly accepted view of attachment and its influence on development. That is, it is important to recognize that attachment security in infancy does not always by itself produce long-term positive outcomes, but rather is linked to later outcomes through connections with the way children and adolescents subsequently experience various social contexts as they develop (O'Connor & others, 2014).

The Van Ryzin, Carlson, and Sroufe (2011) study reflects a **developmental cascade model,** which involves connections across domains over time that influence developmental pathways and outcomes (St. George & others, 2020). Developmental cascades can include connections between a wide range of biological, cognitive, and socioemotional processes (attachment, for example), and also can involve social contexts such as families, peers, schools, and culture. Further, links can produce positive or negative outcomes at different points in development, such as infancy, early childhood, middle and late childhood, adolescence, and adulthood (Kerns & Abtahi. 2020).

developmental cascade model Involves connections across domains over time that influence developmental pathways and outcomes.

A meta-analysis supported the views just described (Pinquart, Feubner, & Ahnert, 2013). In this analysis of 127 research reports, the following conclusions were reached: (1) moderate stability of attachment security occurred from early infancy to adulthood; (2) no significant

stability occurred for time intervals of more than 15 years; (3) attachment stability was greater when the time span was less than 2 years than when it was more than 5 years; and (4) securely attached children at risk were less likely to maintain attachment security, while insecurely attached children at risk were likely to continue to be insecurely attached.

Some developmentalists think that too much emphasis has been placed on the attachment bond in infancy. Jerome Kagan (2000, 2019), for example, emphasizes that infants are highly resilient and adaptive; he argues that they are evolutionarily equipped to stay on a positive developmental course, even in the face of wide variations in parenting. Kagan and others stress that genetic characteristics and temperament play more important roles in a child's social competence than the attachment theorists, such as Bowlby and Ainsworth, are willing to acknowledge (Kim & others, 2017; Simpson & Belsky, 2016). For example, if some infants inherit a low tolerance for stress, this factor, rather than an insecure attachment bond, may be responsible for an inability to get along with peers. One study found links between disorganized attachment in infancy, a specific gene, and levels of maternal responsiveness. In this study, a disorganized attachment style developed in infancy only when infants had the short version of the serotonin transporter gene—5-HTTLPR (Spangler & others, 2009). Infants were not characterized by this attachment style when they had the long version of the gene (Spangler & others, 2009). Further, this gene-environment interaction occurred only when mothers showed a low level of responsiveness toward their infants. Also, a recent research review concluded that DNA methylation associated with infant attachment may influence the stress regulation system and socioemotional function (Craig & others, 2021). However, some researchers have not found support for genetic influences on infant-mother attachment (Leerkes & others, 2017) or for gene-environment interactions related to infant attachment (Roisman & Fraley, 2012).

Another criticism of attachment theory is that it ignores the diversity of socializing agents and contexts that exists in an infant's world. A culture's value system can influence the nature of attachment (Otto & Keller, 2018). Mothers' expectations for infants to be independent are high in northern Germany, whereas Japanese mothers are more strongly motivated to keep their infants close to them (Grossmann & others, 1985; Rothbaum & others, 2000). Not surprisingly, northern German infants tend to show less distress than Japanese infants when separated from their mothers. Also, in some cultures, infants show attachments to many people. Among the Hausa (who live in Nigeria), grandmothers and siblings provide a significant amount of care for infants (Harkness & Super, 1995). Infants in agricultural societies tend to form attachments to older siblings, who are assigned a major responsibility for younger siblings' care. In a recent study in Zambia where siblings were substantially involved in caregiving activities, infants showed strong attachments to both their mothers and their sibling caregivers (Mooya, Sichimba, & Bakermans-Kranenburg, 2016). In this study, secure attachment was the most frequent attachment classification for both mother-infant and sibling-infant relationships.

In the Hausa culture, siblings and grandmothers provide a significant amount of care for infants. *How might these variations in care affect attachment?*
Penny Tweedie/The Image Bank/Getty Images

Researchers recognize the importance of competent, nurturant caregivers in an infant's development (Thompson, 2021). At issue, though, is whether or not secure attachment, especially to a single caregiver, is critical (Verschueren, 2020).

Despite such criticisms, there is ample evidence that security of attachment is important to development (Dagan & Sagi-Schwartz, 2021). Secure attachment in infancy reflects a positive parent-infant relationship and provides a foundation that supports healthy socioemotional development in the years that follow.

Caregiving Styles and Attachment Is the style of caregiving linked with the quality of the infant's attachment? Securely attached babies have caregivers who are sensitive to their signals and are consistently available to respond to their needs (Luby, 2020). These caregivers often let their babies play an active role in determining the onset and pacing of interaction in the first year of life. One study revealed that maternal sensitivity in responding was linked to infant attachment security (Finger & others, 2009). Another study found that maternal sensitivity in parenting was linked to secure attachment in infants in two different cultures: the United States and Colombia (Posada & others, 2002). Further, recent research indicates that if parents who engage in inadequate and problematic caregiving are provided with practice and feedback focused on interacting sensitively with their infants, parent-infant attachment becomes more secure (Dozier, Bernard, & Roben, 2019).

How do the caregivers of insecurely attached babies interact with them? Caregivers of avoidant babies tend to be unavailable or rejecting (Posada & Kaloustian, 2011). They often

What is the nature of secure and insecure attachment? How are caregiving styles related to attachment classification?
George Doyle/Stockbyte/Getty Images

don't respond to their babies' signals and have little physical contact with them. When they do interact with their babies, they may behave in an angry and irritable way. Caregivers of resistant babies tend to be inconsistent; sometimes they respond to their babies' needs and sometimes they don't. In general, they tend not to be very affectionate with their babies and show little synchrony when interacting with them. Caregivers of disorganized babies often neglect or physically abuse them (Almy & Cicchetti, 2018; Carlson, 2021). In some cases, these caregivers are depressed. In sum, caregivers' interactions with infants influence whether infants are securely or insecurely attached to their caregivers (Woodhouse & others, 2019).

Developmental Social Neuroscience and Attachment The emerging field of *developmental social neuroscience* examines connections between socioemotional processes, development, and the brain (Champagne, 2021). Attachment is one of the main areas on which theory and research on developmental social neuroscience has focused. These connections of attachment and the brain involve the neuroanatomy of the brain, neurotransmitters, and hormones.

Theory and research on the role of the brain's regions in mother-infant attachment is just emerging (Storey, Alloway, & Walsh, 2020). One theoretical view proposed that the prefrontal cortex likely has an important role in maternal attachment behavior, as do the subcortical (areas of the brain lower than the cortex) regions of the mother's amygdala (which is strongly involved in emotion) and the hypothalamus (Kim, Strathearn, & Swain, 2016). Research on the role of hormones and neurotransmitters in attachment has emphasized the importance of the neuropeptide hormone oxytocin and the neurotransmitter *dopamine* in the formation of the maternal-infant bond (Feldman, 2019). *Oxytocin*, a mammalian hormone that also acts as a neurotransmitter in the brain, is released in the mother during breast feeding and by contact and warmth. Oxytocin is especially thought to be a likely candidate in the formation of infant-mother attachment (Toepfer & others, 2019). A research review found strong links between levels or patterns of oxytocin production and aspects of mother-infant attachment (Galbally & others, 2011).

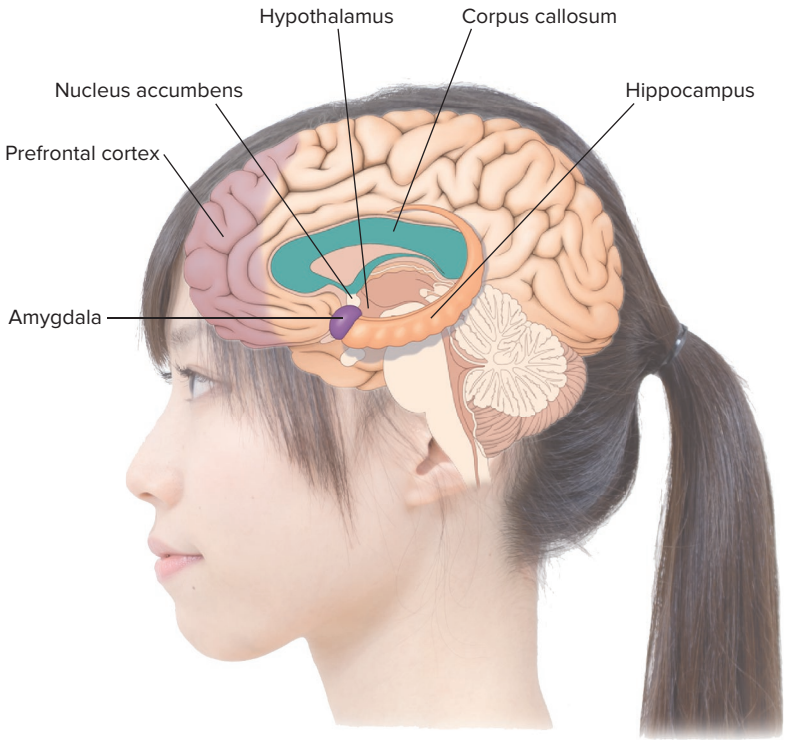


FIGURE **7**

REGIONS OF THE BRAIN PROPOSED AS LIKELY TO BE IMPORTANT IN INFANT-MOTHER ATTACHMENT. This illustration shows the brain's left hemisphere. The corpus callosum is the large bundle of axons that connect the brain's two hemispheres.
(*photo*): Takayuki/Shutterstock

Although oxytocin release is stimulated by birth and lactation in mothers, might it also be released in fathers? Oxytocin is secreted in males, and one research study found that at both 6 weeks and 6 months after birth, when fathers engaged in more stimulation contact with babies, encouraged their exploration, and directed their attention to objects, the fathers' oxytocin levels increased (Gordon & others, 2010).

In mothers, the experience of pleasure and reward influences the brain's dopamine circuits when mothers care for their infants and are exposed to their infants' cues, such as eye contact, smiling, and so on (Feldman, 2019). These experiences and brain changes likely promote mother-infant attachment and sensitive parenting. Also, the influence of oxytocin on dopamine in the mother's nucleus accumbens (a collection of neurons in the forebrain that are involved in pleasure) likely is important in motivating the mother's approach to the baby (de Haan & Gunnar, 2009). Figure 7 shows regions of the brain that are likely to play important roles in infant-mother attachment.

In sum, it is likely that a number of brain regions, neurotransmitters, and hormones are involved in the development of infant-mother attachment (Feldman, 2019). Key candidates for influencing this attachment are connections between the prefrontal cortex, amygdala, and hypothalamus; the nucleus accumbens; and the neuropeptide oxytocin and the neurotransmitter dopamine.

Mothers and Fathers as Caregivers An increasing number of U.S. fathers stay home full-time with their children (Cowan & others, 2019a, b). Recent data indicate that 7 percent of fathers work from home and 24 percent of those fathers care for their children at home (Livingston,

2018). In previous decades, a large portion of the full-time fathers had career-focused wives who provided most of the family's income. However, in 2020, as greater numbers of parents began working at home to maintain social distancing during the COVID-19 pandemic, this likely has changed somewhat and has probably increased the amount of time fathers spend interacting with their children.

Can fathers take care of infants as competently as mothers can? Observations of fathers and their infants suggest that fathers have the ability to care for their infants as sensitively and responsively as mothers do (Cabrera, 2020; Fagan, 2020). Recent studies indicate that when fathers are positively engaged with their children, developmental outcomes are better (Alexander & others, 2017; Roopnarine & Yildirim, 2018).

Consider the Aka pygmy culture in Africa, where fathers spend as much time interacting with their infants as mothers do (Hewlett, 2000; Hewlett & MacFarlan, 2010). Remember, however, that although fathers can be active, nurturing, involved caregivers with their infants, as Aka pygmy fathers are, in many cultures men have not chosen to follow this pattern (Parkinson, 2010).

Do fathers behave differently from mothers when interacting with their infants? Maternal interactions usually center on child-care activities–feeding, changing diapers, bathing (Lamb & Lewis, 2015). Paternal interactions are more likely to include play (Parke, Roisman, & Rose, 2020), and fathers engage in more rough-and-tumble play than mothers do. They bounce infants, throw them up in the air, tickle them, and so on (Lamb, 2013). Mothers do play with infants, but their play is less physical and arousing than that of fathers. Nonetheless, mothers engage in play with their children three times as often as fathers do (Cabrera & Roggman, 2017).

Child Care Many U.S. children today experience multiple caregivers. Most do not have a parent staying home to care for them; instead, the children have some type of care provided by others–"child care." Many parents worry that child care might reduce their infants' emotional attachment to them, impede their infants' cognitive development, fail to teach them how to control anger, and allow them to be unduly influenced by their peers. How extensive is child care? Are the worries of these parents justified?

Parental Leave Today far more young children are in child care than at any other time in history. About 2 million children in the United States currently receive formal, licensed child care, and uncounted millions of children are cared for by unlicensed baby-sitters.

Child-care policies around the world vary in eligibility criteria, duration of parental leaves, benefit level, and the extent to which parents take advantage of the policies (Petersen, 2020). Europe has led the way in creating new standards of parental leave: The European Union (EU) mandated a paid 14-week maternity leave in 1992. In most European countries today, working parents on leave receive 70 to 100 percent of their prior wages, and the duration of paid leave averages about 16 weeks. The United States currently allows workers to take up to 12 weeks of unpaid leave to care for a newborn.

Most countries restrict eligibility for maternity benefits to women who have been employed for a minimum period of time prior to childbirth, but in Denmark even unemployed mothers are eligible for extended parental leave related to childbirth. In Sweden, parents can take an 18-month job-protected parental leave with benefits that can be shared by both parents and applied to full-time or part-time work.

Wanda Mitchell, Child-Care Director

Wanda Mitchell is the Center Director of the Hattie Daniels Day Care Center in Wilson, North Carolina. Her responsibilities include directing the operation of the center, which involves creating and maintaining an environment in which young children can learn effectively as well as ensuring that the center meets state licensing requirements. Mitchell obtained her undergraduate degree from North Carolina A & T University, majoring in child development. Prior to her current position, she was an education coordinator for Project Head Start and an instructor at Wilson Technical Community College. Describing her work, Mitchell says, "I really enjoy working in my field. This is my passion. After graduating from college, my goal was to advance in my field."

PRIMARY CARE ARRANGEMENTS IN THE UNITED STATES FOR CHILDREN UNDER 5 YEARS OF AGE WITH EMPLOYED MOTHERS.

We have all the knowledge necessary to provide absolutely first-rate child care in the United States. What is missing is the commitment and the will.

—Edward Zigler

Contemporary Developmental Psychologist, Yale University

Variations in Child Care Because the United States does not have a policy of paid leave for child care, child care has become a major national concern (Sanders & Guerra, 2016). Many factors influence the effects of child care, including the age of the child, the type of child care, and the quality of the program (Raikes & others, 2020).

Child-care settings in the United States vary extensively (Boller & Harding, 2020). Child care is provided in large centers with elaborate facilities and in private homes. Some child-care centers are commercial operations; others are nonprofit centers run by churches, civic groups, and employers. Some child-care providers are professionals; others are mothers who want to earn extra money. Infants and toddlers are more likely to be found in family child care and informal care settings, while older children are more likely to be in child-care centers and preschool and early education programs. Figure 8 delineates primary care arrangements for U.S. children under 5 years of age with employed mothers (Clarke-Stewart & Miner, 2008).

Child-care quality makes a difference in children's lives (Boller & Harding, 2020). What constitutes a high-quality child-care program for infants? In high-quality child care (Clarke-Stewart & Miner, 2008, p. 273):

> . . . caregivers encourage the children to be actively engaged in a variety of activities, have frequent, positive interactions that include smiling, touching, holding, and speaking at the child's eye level, respond properly to the child's questions or requests, and encourage children to talk about their experiences, feelings, and ideas.

High-quality child care also involves providing children with a safe environment, access to age-appropriate toys and participation in age-appropriate activities, and a low caregiver-to-child ratio that allows caregivers to spend considerable time with children on an individual basis. An Australian study revealed that higher-quality child care that included positive child-caregiver relationships at 2 to 3 years of age was linked to children's better self-regulation of attention and emotion at 4 to 5 and 6 to 7 years of age (Gialamas & others, 2014). Quality of child care matters in children's development, and according to UNICEF, the United States meets or exceeds only 3 of 10 child-care quality benchmarks. An analysis of U.S. child-care studies found that a greater quantity of child care was a strong predictor of socioemotional problems (Jacob, 2009). To read about one individual who provides quality child care to individuals from impoverished backgrounds in the United States, see the *Connecting with Careers* profile.

A major, ongoing longitudinal study of U.S. child care was initiated by the National Institute of Child Health and Human Development (NICHD) in 1991. Data were collected on a diverse sample of almost 1,400 children and their families at ten locations across the United States over a period of seven years. Researchers used multiple methods (trained observers,

interviews, questionnaires, and testing), and they measured many facets of children's development, including physical health, cognitive development, and socioemotional development. Following are some of the results of what is now referred to as the NICHD Study of Early Child Care and Youth Development, or NICHD SECCYD (NICHD Early Child Care Research Network, 2001, 2002, 2005, 2006, 2010).

- *Patterns of use*. Many families placed their infants in child care very soon after the child's birth, and there was considerable instability in the child-care arrangements. By 4 months of age, nearly three-fourths of the infants had entered some form of nonmaternal child care. Almost half of the infants were cared for by a relative when they first entered care; only 12 percent were enrolled in child-care centers. Low-income families were more likely than more affluent families to use child care, but infants from low-income families who were in child care averaged the same number of hours of child care as other income groups. In the preschool years, mothers who were single, those with more education, and families with higher incomes used more hours of center-based care than other families. Minority families and mothers with less education used more hours of care by relatives.
- *Quality of care*. Evaluations of quality of care were based on characteristics such as group size, child–adult ratio, physical environment, caregiver characteristics (such as formal education, specialized training, and child-care experience), and caregiver behavior (such as sensitivity to children). An alarming conclusion is that a majority of the child care in the first three years of life was of unacceptably low quality. Positive caregiving by nonparents in child-care settings was infrequent—only 12 percent of the children studied were experiencing positive nonparental child care (such as positive talk and language stimulation)! Further, infants from low-income families experienced a lower quality of child care than infants from higher-income families. When quality of care was high, children performed better on cognitive and language tasks, were more cooperative with their mothers during play, showed more positive and skilled interaction with peers, and had fewer behavior problems. Caregiver training and good child-to-staff ratios were linked with higher cognitive and social competence when children were 54 months of age.
- *Amount of child care*. In general, when children spent 30 hours or more per week in child care, their development was less than optimal (Ramey, 2005).
- *Family and parenting influences*. The influence of families and parenting was not weakened by extensive child care. Parents played a significant role in helping children to regulate their emotions. Especially important parenting influences were being sensitive to children's needs, being involved with children, and cognitively stimulating them. Indeed, parental sensitivity has been the most consistent predictor of a secure attachment, with child-care experiences being relevant in many cases only when mothers engage in insensitive parenting (Friedman, Melhuish, & Hill, 2011). An important point about the extensive NICHD research is that findings show that family factors are considerably stronger and more consistent predictors of a wide variety of child outcomes than are child-care aspects such as quality, quantity, and type. That said, a recent NICHD study found that sensitive, nurturing care at home and in child-care settings from 6 to 54 months predicted a higher incidence of prosocial behavior in first-grade children (Brownell & Drummond, 2020).
- *Home and child-care settings.* The worst outcomes for children occur when both home and child-care settings are of poor quality. For example, one study involving the NICHD SECCYD data revealed that worse socioemotional outcomes (higher levels of problem behavior, lower levels of prosocial behavior) for children occurred when they experienced both home and child-care environments that conferred risk (Watamura & others, 2011).

What are some important findings from the national longitudinal study of child care conducted by the National Institute of Child Health and Human Development?
Reena Rose Sibayan/The Jersey Journal/Landov Images

What are some strategies parents can follow in regard to child care? Child-care expert Kathleen McCartney (2003, p. 4) offered this advice:

- *Recognize that the quality of your parenting is a key factor in your child's development.*
- *Make decisions that will improve the likelihood you will be good parents.* "For some this will mean working full-time"—for personal fulfillment, income, or both. "For others, this will mean working part-time or not working outside the home."
- *Monitor your child's development.* "Parents should observe for themselves whether their children seem to be having behavior problems." If problems arise, parents need to talk with their child-care providers and their pediatrician about their child's behavior.
- *Take some time to find the best child care.* Observe different child-care facilities and be certain that you like what you see. "Quality child care costs money, and not all parents can afford the child care they want. However, state subsidies, and other programs like Head Start, are available for families in need."

Attachment in Middle and Late Childhood Earlier you read about the importance of secure attachment in infancy and the role of sensitive parenting in attachment (Dagan & Sagi-Schwartz, 2021). The attachment process continues to be an important aspect of children's development in the childhood years. In middle and late childhood, attachment becomes more sophisticated, and as children's social worlds expand to include peers, teachers, and others, they typically spend less time with parents.

Kathryn Kerns and her colleagues (Kerns & Abtahi, 2020; Kerns & Brumariu, 2014, 2016; Koehn & Kerns, 2018) have studied links between attachment to parents and various child outcomes in middle and late childhood. Secure attachment was associated with a lower level of internalized symptoms, anxiety, and depression in children (Brumariu & Kerns, 2011), as well as a higher level of children's emotion regulation and less difficulty in identifying emotions (Kerns & Brumariu, 2014).

Might certain parenting behaviors be associated with different attachment categories in children and adolescents? In recent research, a series of meta-analyses of 5- to 18-year-olds found that parents of children who were more securely attached were more responsive, provided better support of their children's autonomy, and were less punitive (Koehn & Kerns, 2018). Also in this research, parents of children who showed more avoidant attachment were less responsive and more punitive, while no association was found between parenting behaviors and ambivalent (insecure resistant) attachment in children.

ADOLESCENCE

Relationships between parents and children continue to be important during the adolescent years. But the adolescent's emotions may become more involved with people outside the family, especially with romantic partners. What do psychologists know about these relationships?

Attachment to Parents Initial research interest in attachment focused on infants and their caregivers (Thompson, Simpson, & Berlin, 2021a, b). Developmentalists have recently begun to explore the role of secure attachment and related concepts, such as connectedness to parents, during adolescence (Allen, 2021; Marci & others, 2021). In a research review, the most consistent outcomes of secure attachment in adolescence involved positive peer relations and development of the adolescent's capacity to regulate emotions (Allen & Miga, 2010). Researchers also have found that securely attached adolescents are less likely than those who are insecurely attached to have emotional difficulties and to engage in problem behaviors such as drug abuse (Theoret & others, 2021). For example, a recent study of Lebanese adolescents revealed that those who were securely attached had lower rates of addiction to alcohol and cigarettes than their insecurely attached counterparts (Nakhoul & others, 2020). In addition, a recent Israeli study found that avoidant and anxiously attached adolescents were less effective in coping with stress (Agbaria, 2021). In another recent study, delinquent and maltreated adolescents had high levels of insecure attachment (Protic & others, 2020). In sum, just as in infancy, secure attachment to parents during adolescence is an important aspect of parent-adolescent relationships and is linked to a wide range of positive outcomes for adolescents (Rowe, Gold, & Carnelley, 2020).

Dating and Romantic Relationships Adolescents not only have attachments to their parents but also to romantic partners (Shulman & others, 2020). Adolescents spend considerable time either dating or thinking about dating, which has gone far beyond its original courtship function to become a form of recreation, a source of status and achievement, and a setting for learning about close relationships (Davila, Capaldi, & La Greca, 2016; Furman & Rose, 2015). One function of dating, though, continues to be mate selection.

Types of Dating and Developmental Changes Three stages characterize the development of romantic relationships in adolescence (Connolly & McIsaac, 2009):

- *Entry into romantic attractions and affiliations at about 11 to 13 years of age*. This initial stage is triggered by puberty. From 11 to 13, adolescents become intensely interested in romance, and it dominates many conversations with same-sex friends. Developing a crush on someone is common, and the crush often is shared with a same-sex friend. Young adolescents may or may not interact with the individual who is the object of their infatuation. When dating occurs, it usually takes place in a group setting.
- *Exploring romantic relationships at approximately 14 to 16 years of age*. At this point in adolescence, two types of romantic involvement occur: casual dating and group dating. Casual dating emerges between individuals who are mutually attracted. These dating experiences are often short-lived, last a few months at best, and usually endure for only a few weeks. *Dating in groups* is common and reflects embeddedness in the peer context. A friend often acts as a third-party facilitator of a potential dating relationship by communicating their friend's romantic interest and determining whether this attraction is reciprocated.
- *Consolidating dyadic romantic bonds at about 17 to 19 years of age*. At the end of the high school years, more serious romantic relationships develop. Romantic relationships within this age group are characterized by strong emotional bonds more closely resembling those in adult romantic relationships. These bonds often are more stable and enduring than earlier bonds, typically lasting one year or more.

Two variations on these stages in the development of romantic relationships in adolescence involve early and late bloomers (Connolly & McIsaac, 2009). Early bloomers include 15 to 20 percent of 11- to 13-year-olds who say that they currently are in a romantic relationship and 35 percent who indicate that they have had some prior experience in romantic relationships. One study found that early daters had more externalized problems throughout adolescence than on-time daters and late bloomers (Connolly & others, 2013). Late bloomers comprise approximately 10 percent of 17- to 19-year-olds who say that they have had no experience with romantic relationships and another 15 percent who report that they have not engaged in any romantic relationships that lasted more than four months.

Dating and Adjustment Researchers have linked dating and romantic relationships with various measures of how well adjusted adolescents are (Shulman & others, 2020). For example, a study of 200 tenth-graders revealed that those with more romantic experiences reported higher levels of social acceptance, friendship competence, and romantic competence—however, having more romantic experience also was linked with a higher level of substance use, delinquency, and sexual behavior (Furman, Low, & Ho, 2009). Dating and romantic relationships at an early age can be especially problematic (Connolly & McIsaac, 2009). One study found that romantic activity was linked to depression in early adolescent girls (Starr & others, 2012). Researchers also have found that early dating and "going with" someone are linked with adolescent pregnancy and problems at home and school (Florsheim, Moore, & Edgington, 2003). However, in some cases, romantic relationships in adolescence are linked with positive developmental changes. For example, in a recent study, having a supportive romantic relationship in adolescence was linked to positive outcomes for adolescents who had negative relationships with their mothers (Szwedo, Hessel, & Allen, 2017).

Sociocultural Contexts and Dating The sociocultural context is a strong influence on adolescents' dating patterns (Furman, 2018). Values and religious beliefs of various cultures often dictate the age at which dating begins, how much freedom in dating is allowed, whether dates must be chaperoned by adults or parents, and the roles of males and females in dating. For example, Latinx and Asian American cultures have more conservative standards regarding adolescent dating than does the Anglo-American culture.

What are dating relationships like in adolescence?
Digital Vision/Getty Images

Dating may be a source of cultural conflict for many adolescents whose families come from cultures in which dating begins at a later age with little freedom, especially for adolescent girls. One study found that Asian American adolescents were less likely to have been involved in a romantic relationship in the past 18 months than African American or Latinx adolescents (Carver, Joyner, & Udry, 2003). A recent study found that mother-daughter conflict in Mexican American families was linked to an increase in adolescent daughters' romantic involvement (Tyrell & others, 2016). When immigrant adolescents choose to adopt the ways of the dominant U.S. culture (such as unchaperoned dating), they often clash with parents and extended-family members who have more traditional values.

ADULTHOOD

Attachment and romantic relationships continue to be very important aspects of close relationships in adulthood. Let's explore attachment first, then examine different types of love.

Attachment Earlier in this chapter, we discussed the importance of attachment in infancy, childhood, and adolescence (Dagan & Sagi-Schwartz, 2021; Shulman & others, 2020). Are these earlier patterns of attachment related to adults' attachment styles?

Linking Infant Attachment to Adult Attachment Although relationships with romantic partners differ from those with parents, romantic partners fulfill some of the same needs for adults as parents do for their children (Mikulincer & Shaver, 2019, 2021). Recall that *securely attached* infants are defined as those who use the caregiver as a secure base from which to explore the environment (Thompson, Simpson, & Berlin, 2021a, b). Similarly, adults may count on their romantic partners to be a secure base to which they can return and obtain comfort and security in stressful times (Fraley & Shaver, 2021).

Do adult attachment patterns with partners reflect childhood attachment patterns with parents? In a retrospective study, Cindy Hazan and Phillip Shaver (1987) found that young adults who were securely attached in their romantic relationships were more likely to describe their early relationship with their parents as securely attached. In a longitudinal study, infants who were securely attached at 1 year of age were securely attached 20 years later in their adult romantic relationships (Steele & others, 1998). Also, a longitudinal study revealed that securely attached infants were in more stable romantic relationships in adulthood than their insecurely attached counterparts (Salvatore & others, 2011). However, in another longitudinal study the links between early attachment styles and later attachment styles were weakened by stressful and disruptive experiences such as the death of a parent or instability of caregiving (Lewis, Feiring, & Rosenthal, 2000).

Adult Attachment Styles Hazan and Shaver (1987) measured attachment styles using the following brief assessment.

Read each paragraph and then place a check mark next to the one that best describes your interactions with others:

1. I find it relatively easy to get close to others and I am comfortable depending on them and having them depend on me. I don't worry about being abandoned or about someone getting too close to me.
2. I am somewhat uncomfortable being close to others. I find it difficult to trust them completely and to allow myself to depend on them. I get nervous when anyone gets too close to me, and it bothers me when someone tries to be more intimate with me than I feel comfortable with.
3. I find that others are reluctant to get as close as I would like. I often worry that my partner doesn't really love me or won't want to stay with me. I want to get very close to my partner, and this sometimes scares people away.

These items correspond to three attachment styles—secure attachment (option 1 in the list) and two insecure attachment styles (avoidant—option 2, and anxious—option 3):

secure attachment style An attachment style that describes adults who have positive views of relationships, find it easy to get close to others, and are not overly concerned or stressed out about their romantic relationships.

- **Secure attachment style.** Securely attached adults have positive views of relationships, find it easy to get close to others, and are not overly concerned with, or stressed out about, their romantic relationships. These adults tend to enjoy sexuality in the context of a committed relationship and are less likely than others to have one-night stands.

How are attachment patterns in childhood linked to relationships in emerging and early adulthood?
(*left*): Ai/Getty Images; (*right*): Jade/Blend Images/Getty Images

- **Avoidant attachment style.** Avoidant individuals are hesitant about getting involved in romantic relationships and once in a relationship tend to distance themselves from their partner.
- **Anxious attachment style.** These individuals demand closeness, are less trusting, and are more emotional, jealous, and possessive.

The majority of adults (about 60 to 80 percent) describe themselves as securely attached, and not surprisingly adults prefer having a securely attached partner (Zeifman & Hazan, 2008).

Researchers are studying links between adults' current attachment styles and many aspects of their lives (Fraley & Shaver, 2021; Mikulincer & Shaver, 2021). For example, securely attached adults are more satisfied with their close relationships than insecurely attached adults, and the relationships of securely attached adults are more likely to be characterized by trust, commitment, and longevity. In a recent research review, having a secure attachment style acted as a protective factor in lowering suicidal risk, while insecure attachment styles compromised an individual's ability to cope with relationship issues, which increased suicidal risk (Zortea, Gray, & O'Connor, 2021). Also, in a recent study, college students with an anxious attachment style were more likely to be addicted to social networking sites (Liu & Ma, 2019). And in a recent meta-analysis, adults with insecure attachment styles were more likely to engage in risky sexual behaviors (Kim & Miller, 2020). Further, researchers recently have found that insecure anxious and insecure avoidant individuals are more likely than securely attached individuals to engage in risky health behaviors and that they tend to be more susceptible to physical illness and to have poorer disease outcomes (Pietromonaco & Beck, 2018).

Leading experts Mario Mikulincer and Phillip Shaver (2019, 2021) have reached the following conclusions about the benefits of secure attachment:

1. Individuals who are securely attached have a well-integrated sense of self-acceptance, self-esteem, and self-efficacy.
2. They have the ability to control their emotions, are optimistic, and are resilient.
3. Facing stress and adversity, they activate cognitive representations of security, are mindful of what is happening around them, and mobilize effective coping strategies.

If you have an insecure attachment style, are you stuck with it and does it doom you to have problematic relationships? Attachment categories are somewhat stable in adulthood, but

What are some key dimensions of attachment in adulthood, and how are they related to relationship patterns and well-being?

avoidant attachment style An attachment style that describes adults who are hesitant about getting involved in romantic relationships and, once in a relationship, tend to distance themselves from their partner.

anxious attachment style An attachment style that describes adults who demand closeness, are less trusting, and are more emotional, jealous, and possessive.

What are some changes in attachment in older adults?
Purestock/SuperStock

adults do have the capacity to change their attachment thinking and behavior (Mikulincer & Shaver, 2019, 2021). Although attachment insecurities are linked to relationship problems, attachment style makes only a moderate contribution to relationship functioning because other factors contribute to relationship satisfaction and success. In the chapter on "Families, Lifestyles, and Parenting," we will discuss such factors in our coverage of marital relationships.

Attachment from Early to Late Adulthood There has been far less research on how attachment influences the lives of aging adults than on effects of attachment in children, adolescents, and young adults (Fraley, 2019; Fraley & Shaver, 2021). A large-scale study examined attachment anxiety and avoidance in individuals from 18 to 70 years of age (Chopik, Edelstein, & Fraley, 2013). In this study, attachment anxiety was highest among adults in their mid-twenties and lowest among middle-aged and older adults. Developmental changes in avoidant attachment were not as strong as in anxious attachment, although anxious attachment was highest for middle-aged adults and lowest for young adults and older adults. Also, in related longitudinal data involving individuals from 13 to 72 years of age, avoidant attachment declined across the lifespan and being in a relationship predicted lower levels of anxious and avoidant attachment across adulthood (Chopik, Edelstein, & Grimm, 2019). Further, a recent study of older adult women found that avoidant attachment was linked to higher levels of social isolation (Spence, Jacobs, & Bifulco, 2020). And a recent study of older adults indicated that attachment security was linked to competence in daily life, which in turn was related to psychological adjustment (Martin, Horn, & Allemand, 2021).

Romantic Love Think for a moment about songs and books that hit the top of the charts. Chances are, they're about love. Poets, playwrights, and musicians through the ages have lauded the fiery passion of romantic love—and lamented the searing pain when it fails. **Romantic love** is also called *passionate love* or *eros;* it has strong components of sexuality and infatuation, and it often predominates in the early part of a love relationship. A meta-analysis found that males show higher avoidance and lower anxiety about romantic love than females do (Del Giudice, 2011).

Well-known love researcher Ellen Berscheid (1988) says that romantic love is what we mean when we say that we are "in love" with someone. It is romantic love, she stresses, that we need to understand if we are to learn what love is all about. According to Berscheid, sexual desire is the most important ingredient of romantic love. We discuss sexuality in more detail in the chapter on "Gender and Sexuality."

Romantic love includes a complex intermingling of emotions—fear, anger, sexual desire, joy, and jealousy, for example. Obviously, some of these emotions are a source of anguish. One study found that romantic lovers were more likely than friends to be the cause of depression (Berscheid & Fei, 1977). Another study revealed that a heightened state of romantic love in young adults was linked to stronger depression and anxiety symptoms but better sleep quality (Bajoghli & others, 2014). Other researchers found that declaring a relationship status on Facebook was associated with both romantic love and jealousy (Orosz & others, 2015).

Do romantic relationships have components that go beyond mutual sexual desire and strong emotions? In a recent study, being in a romantic relationship, time spent interacting with a partner, and investing more time and effort in the relationship all predicted greater well-being (Hudson, Lucas, & Donnellan, 2020). However, these effects were moderated by relationship quality, as researchers found that being in a relatively neutral relationship was associated with lower well-being than being unpartnered.

Recently, romantic attraction has not only taken place in person but also over the Internet (Jin, Ryu, & Mugaddam, 2019; Lenton-Brym & others, 2021). Forty million Americans use online dating services (about 40 percent of the U.S. singles pool) (Broussard, 2015). Is looking for love online more likely to be successful than meeting a potential partner face-to-face? It didn't work out well for Notre Dame linebacker Manti Te'o, whose online girlfriend turned out to be a "catfish," someone who fakes an identity online. However, online dating sites claim that their sites often have positive outcomes. A poll commissioned by match.com reported that twice as many marriages occurred between individuals who met through an online dating site as between people who met in bars, clubs, and other social settings.

A recent national poll of more than 5,000 singles in the United States provided information about how singles navigated dating during the COVID-19 pandemic (Match.com, 2020). In this poll, singles were making more time for their romantic search, refining what they wanted in a partner, and rethinking how and where they would search for love. Almost 60 percent of single app daters shifted toward more intentional dating in the face of the COVID-19 pandemic. Two-

thirds said they were ready to go on an in-person date, but 36 percent indicated they would be more selective about who they would go out with and where they would go on a date.

Barbara Hassan, a 47-year-old divorcee from Texas, registered with match.com and within one day had three matches, all of whom appeared to be intelligent, attractive, and well off (Marinova, 2013). Barbara's first thoughts were that they were too good to be true, and those first thoughts were right. One of her matches said he was a construction engineer from Nigeria who had designed a building for orphans. She communicated with him for several months and then he asked her to send him $2,700 so he could come to the United States. That was enough to end the connection.

Connecting online for love turned out positively for two Columbia University graduate students, Michelle Przybyksi and Andy Lalinde (Steinberg, 2011). They found out they lived only a few blocks away from each other, so soon after they communicated online through Datemyschool.com, a dating site exclusively for college students, they met in person, really hit it off, applied for a marriage license 10 days later, and eventually got married.

However, in an editorial in *The Tower*, the student newspaper at Arcadia University in Philadelphia, Samantha Nickalls (2012) argued that online dating sites might be okay for people in their thirties and older but not for college students. She commented:

> The dating pool of our age is huge. Huge. After all, marriage is not on most people's minds when they're in college, but dating (or perhaps just hooking up) most certainly is. A college campus, in fact, is like living a dating service because the majority of people are looking for the same thing you are. As long as you put yourself out there, flirt a bit, and be friendly, chances are that people will notice.
>
> If this doesn't work for you right away, why should it really matter? As a college student, you have so many other huge things going on in your life—your career choice, your transition from kid to adult, your crazy social life. Unless you are looking to get married at age 20 (which is a whole other issue that I could debate for hours), dating shouldn't be the primary thing on your mind anyway. Besides, as the old saying goes, the best things come when you least expect them. Oftentimes, you find the best dates by accident—not by hunting them down.

Some critics argue that online romantic relationships lose the interpersonal connection, whereas others emphasize that the Internet may benefit shy or anxious individuals who find it difficult to meet potential partners in person (Holmes, Little, & Welsh, 2009). One problem with online matchmaking is that many individuals misrepresent their characteristics, such as how old they are, how attractive they are, and their occupation. Recent data indicate that men lie most about their age, height, and income; women lie most about their weight, physical build, and age (statisticbrain.com, 2017). Despite such dishonesty, researchers have found that romantic relationships initiated on the Internet are more likely than relationships established

Love is a canvas furnished by nature and embroidered by imagination.

in person to last for more than two years (Bargh & McKenna, 2004). And in a large-scale study of more than 19,000 individuals, it was discovered that more than one-third of relationships that lead to marriage now begin online and that the resulting marriages are slightly less likely to break up and are characterized by slightly higher marital satisfaction than marriages that begin with contact in offline contexts (Cacioppo & others, 2013).

Developmental Changes How do romantic relationships change in emerging adulthood? In a recent study that spanned 10 years, short-term relationships were more common as individuals moved into emerging adulthood (Lantagne & Furman, 2017). Long-term adolescent relationships were both supportive and turbulent, characterized by elevated levels of support, negative interactions, higher control, and more jealousy. In emerging adulthood, long-term relationships provided high levels of support as well as decreased levels of negative interactions, control, and jealousy.

Cross-Cultural Variations Culture has strong influences on many aspects of human development, including romantic relationships (Luo, 2019). In collectivist countries like China and Korea, intimacy is more diffused in love because of the strong group emphasis on connections outside of a romantic love relationship. By contrast, in individualistic countries such as the United States and most European countries, intimacy is often more intensified because an individual's social network is more likely to be smaller and less group-oriented (Gao, 2016). Also, research indicates that greater passion characterizes U.S. romantic relationships compared with Chinese romantic relationships (Gao, 2001). And researchers have found that self-disclosure is more common in U.S. romantic relationships than in Japanese romantic relationships (Kito, 2005). However, feelings of commitment are stronger in Chinese romantic relationships than in U.S. romantic relationships (Dion & Dion, 1993).

In an exploration of cross-cultural variations, romantic relationships were studied in four countries—Japan, Argentina, France, and Qatar (Ansari, 2015). In Japan, the marriage rate is declining so rapidly that the Japanese government is very concerned that this could lead to a considerable drop in Japan's population. In 2013, 45 percent of Japanese women 16 to 24 years of age reported that they were not interested in or despised having sexual contact. Also, the percentage of Japanese men and women who aren't involved in any romantic relationship has increased significantly in recent years.

In Argentina, romantic interest is much stronger than in Japan (Ansari, 2015). Sexual and romantic flirtation is a way of life for many Argentinians. Online dating is not nearly as frequent as in the United States, apparently because men are so forward in their romantic pursuits in person.

In France, as in Argentina, interest in passionate love is strong. However, in comparison with Japan, Argentina, and the United States, one aspect of French interest in romantic relationships stood out—their affinity for having extramarital affairs. In one comparison, only 47 percent of survey respondents in France stated that having an extramarital affair is morally wrong, compared with 69 percent in Japan, 72 percent in Argentina, and 84 percent in the United States (Wike, 2014). In sum, there are striking cultural variations in many aspects of romantic relationships.

Affectionate Love

Love is more than just passion (Hanley, 2020). **Affectionate love,** also called companionate love, is the type of love that occurs when individuals desire to have the other person near and have a deep, caring affection for the person.

There is a growing belief that as love matures, passion tends to give way to affection (Sternberg, 2013). One investigation interviewed 102 happily married couples in early (average age 28), middle (average age 45), and late (average age 65) adulthood to explore the nature of age and sex differences in satisfying love relationships (Reedy, Birren, & Schaie, 1981). As indicated in Figure 9, communication was more important in early adulthood, sexual intimacy was more important in early to middle adulthood, and feelings of emotional security and loyalty were more important in later-life love relationships. Young adult lovers also rated communication as more characteristic of their love than their older counterparts did. Aside from the age differences, however, there were some striking similarities in the nature of satisfying love relationships. At all ages, emotional security was ranked as the most important factor in love, followed by respect, communication, help and play behaviors, sexual intimacy, and loyalty. The findings of this research also suggested that women believe emotional security is more important in love than men do.

affectionate love Also called companionate love, this type of love occurs when individuals desire to have another person nearby and have a deep, caring affection for the person.

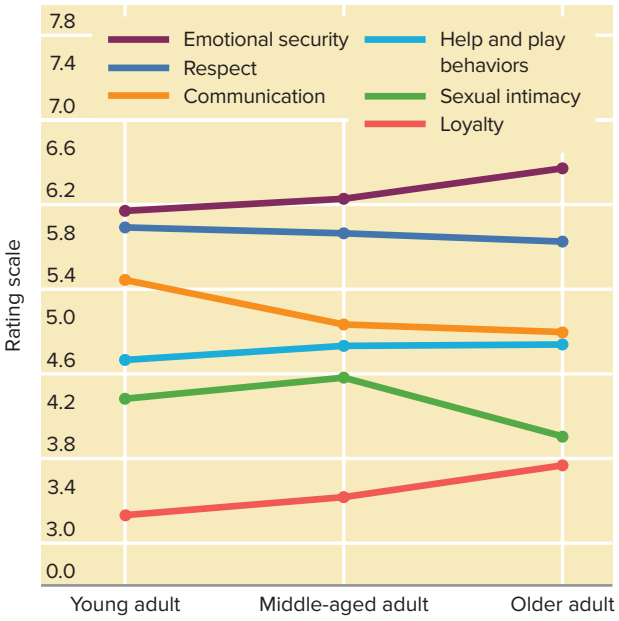

FIGURE 9

CHANGES IN SATISFYING LOVE RELATIONSHIPS ACROSS THE ADULT YEARS. In the investigation by Reedy, Birren, and Schaie (1981), emotional security was the most important factor in love at all ages. Sexual intimacy was more important in early adulthood, whereas emotional security and loyalty were more important in the love relationships of older adults. Young adult lovers also rated communication as more important in a love relationship than their older counterparts did.

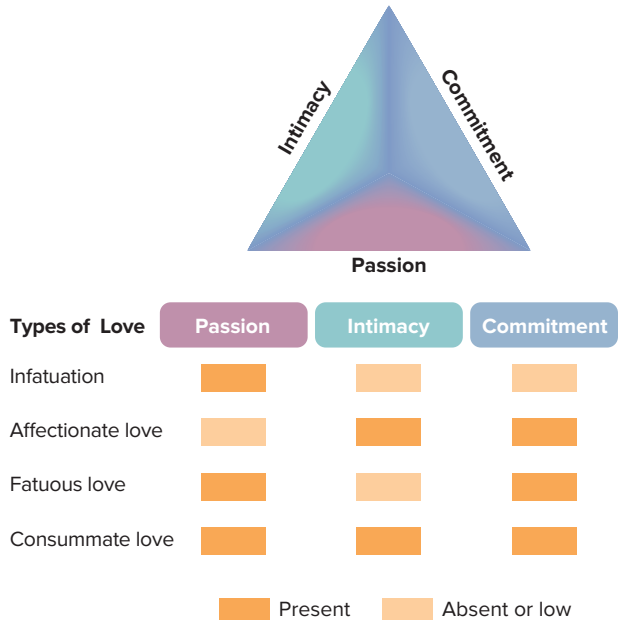

FIGURE 10

STERNBERG'S TRIANGLE OF LOVE. Sternberg identified three dimensions that shape the experience we call love: passion, intimacy, and commitment. Various combinations of the three dimensions produce particular types of love.

Sternberg's Triangular Theory of Love

Clearly, there is more to satisfying love relationships than sex (Moor, Haimov, & Shreiber, 2021). One theory of love that captures this idea has been proposed by Robert J. Sternberg (1988, 2013, 2021d, 2022). His **triangular theory of love** states that love has three main components or dimensions—passion, intimacy, and commitment (see Figure 10):

- *Passion*, as described earlier, is physical and sexual attraction to another.
- *Intimacy* is the emotional feelings of warmth, closeness, and sharing in a relationship.
- *Commitment* is each partner's cognitive appraisal of the relationship and their intent to maintain the relationship even in the face of problems.

According to Sternberg, if passion is the only ingredient (with intimacy and commitment low or absent), we are merely experiencing infatuation. This might happen in an affair or a one-night stand. But varying combinations of the dimensions of love create three qualitatively different types of love:

- A relationship marked by intimacy and commitment but low or lacking in passion is called *affectionate love,* a pattern often found among couples who have been married for many years.
- If passion and commitment are present but intimacy is not, Sternberg calls the relationship *fatuous* love, as when one person worships another from a distance.
- If passion, intimacy, and commitment are all strong, the result is *consummate love*, the fullest type of love.

In a recent cross-cultural study of more than 7,000 individuals in 25 countries, the universality of Sternberg's triarchic theory was confirmed (Sorokowski & others, 2021).

What happens when a person is in love with someone who doesn't feel the same way? To learn more about unrequited love, see the *Connecting with Research* interlude.

triangular theory of love Sternberg's theory that love includes three components or dimensions—passion, intimacy, and commitment.

How Can I Move On with Unrequited Love?

Eddie Clark

Key Points:

- unrequited love
- motivation to remain friends after being rejected
- strong friendship prior to rejection is best predictor

Dr. Eddie Clark, a psychology professor and researcher at St. Louis University, has explored the dynamics of close relationships, including unrequited love (Clark, 2021). When one person is passionately in love with another, confesses love to the other, but the other doesn't feel the same way, the person experiences unrequited love. In a study of 235 undergraduate psychology students, Clark and his colleagues (2020) explored the desire to remain friends after such a rejection of love. Participants were asked about their most recent love rejection, their motivation to remain friends (or not), and their level of break-up distress.

On average, the study participants (called pursuers) had known the other person for about 2.5 years before confessing their love, and the rejection had occurred about two years prior to the data collection. The researchers revealed that the amount of time spent developing a strong friendship prior to the rejection event was the most powerful predictor of the desire to remain friends afterward. Pursuers who waited longer to confess their love indicated that even after the rejection, they wanted to maintain their friendship because the other person still brought something special to their lives and was someone they still cared about. Pursuers referred to how much their friends and family liked the other person as part of their motivation to remain friends. When a strong friendship is built first, unrequited love does not always end the friendship.

Emotional Development and Attachment

1 Exploring Emotion

LG1 Discuss basic aspects of emotion.

What Are Emotions?

- Emotion is feeling, or affect, that expresses the pleasantness or unpleasantness of a person's state; it occurs when a person is engaged in an interaction that is important to him or her, especially to his or her well-being. Emotions can be classified as positive or negative and vary in intensity.

- Darwin described the evolutionary basis of emotions, and today psychologists note that emotions, especially facial expressions of emotions, have a biological foundation.
- Facial expressions of emotion are similar across cultures, but display rules are not culturally universal. Biological evolution endowed humans to be emotional, but culture and relationships with others provide diversity in emotional experiences.
- Children's cognitive processing, such as their attention, influences their emotional development.

Emotion Regulation

- The ability to control one's emotions is a key dimension of development. Emotion regulation consists of effectively managing arousal to adapt and reach a goal. In infancy and early childhood, regulation of emotion gradually shifts from external sources to self-initiated, internal sources. As children mature, they are likely to increase their use of cognitive strategies for regulating emotion, modulate their emotional arousal, become more adept at managing situations to minimize negative emotion, and choose effective ways to cope with stress. Emotion-coaching parents are more likely to have children who engage in effective self-regulation of their emotions than are emotion-dismissing parents.

Emotional Competence

- Saarni argues that becoming emotionally competent involves developing a number of skills such as being aware of one's emotional states, discerning others' emotions, adaptively coping with negative emotions, and understanding the role of emotions in relationships.

2 Development of Emotion

LG2 Describe the development of emotion through the life span.

Infancy

- Infants display a number of emotions early in the first six months, including sadness, surprise, interest, joy, fear, and anger—although researchers debate the onset and sequence of these emotions. Lewis distinguishes between primary emotions and self-conscious emotions.
- Crying is the most important mechanism newborns have for communicating with their world. Babies have at least three types of cries—basic, anger, and pain cries. Controversy surrounds the question of whether babies should be soothed when they cry, although increasingly experts recommend immediately responding in a caring way during the first year.
- Social smiling in response to a caregiver's voice occurs as early as 4 weeks of age. Two fears that infants develop are stranger anxiety and separation from a caregiver (which is reflected in separation protest).

Early Childhood

- Young children's range of emotions expands during early childhood as they increasingly experience self-conscious emotions such as pride, shame, and guilt. Between 2 and 4 years of age, children use an increasing number of terms to describe emotion and learn more about the causes and consequences of feelings. At 4 to 5 years of age, children show an increased ability to reflect on emotions and understand that a single event can elicit different emotions in different people. Emotion regulation is a key aspect of competent socioemotional development in childhood.

Middle and Late Childhood

- In middle and late childhood, children show a growing awareness of the need to control and manage emotions to meet social standards. During this age period, they show enhanced emotional understanding, markedly improve their ability to suppress or conceal negative emotions, use self-initiated strategies for redirecting feelings, have an increased tendency to take into fuller account the events that lead to emotional reactions, and develop a genuine capacity for empathy.

Adolescence

- As individuals go through early adolescence, they are less likely to report being very happy. Moodiness is a normal aspect of early adolescence. Although pubertal change is associated with an increase in negative emotions, hormonal influences are often small, and environmental experiences may contribute more to the emotions of adolescents than hormonal changes do.

Adult Development and Aging

- Older adults are better at controlling their emotions than younger adults are, and older adults experience more positive and less negative emotions than younger adults do. An important theory regarding developmental changes in emotion during adulthood, especially late adulthood, is Carstensen's socioemotional selectivity theory. Knowledge-related and emotion-related goals change across the life span; emotion-related goals become more important when individuals get older.

3 Temperament

LG3 Characterize variations in temperament and their significance.

Describing and Classifying Temperament

- Temperament is an individual's behavioral style and characteristic way of emotional responding. Developmentalists are especially interested in the temperament of infants. Chess and Thomas classified infants as (1) easy, (2) difficult, or (3) slow to warm up. Kagan argues that inhibition to the unfamiliar is an important temperament category. Rothbart and Bates' view of temperament identifies three aspects: (1) extraversion/surgency, (2) negative affectivity, and (3) effortful control (self-regulation).

Biological Foundations and Experience

- Physiological characteristics are associated with different temperaments, and a moderate influence of heredity has been found in studies of the heritability of temperament. Children inherit a physiology that biases them to have a particular type of temperament, but through experience they learn to modify their temperament style to some degree.
- Very active young children are likely to become outgoing adults. In some cases, a difficult temperament is linked to adjustment problems in early adulthood. The link between childhood temperament and adult personality depends in part on context, which helps shape the reaction to a child and thus the child's experiences. For example, the reaction to a child's temperament depends in part on the child's culture.

Goodness of Fit and Parenting

- Goodness of fit refers to the match between a child's temperament and the environmental demands the child must cope with. Goodness of fit can be an important aspect of a child's adjustment. Although research evidence is sketchy at this time, some general recommendations are that caregivers should (1) be sensitive to the individual characteristics of the child, (2) be flexible in responding to these characteristics, and (3) avoid negative labeling of the child.

4 Attachment and Love

LG4 Explain attachment and its development.

Infancy and Childhood

- Infants show a strong interest in the social world and are motivated to understand it. Infants orient to the social world early in their development. Face-to-face play with a caregiver begins to occur at about 2 to 3 months of age. Newly developed self-produced locomotor skills significantly expand the infant's ability to initiate social interchanges and explore his or her social world more independently. Perceiving people as engaging in intentional and goal-directed behavior is an important social cognitive accomplishment that occurs toward the end of the first year. Social referencing increases in the second year of life.
- Attachment is a close emotional bond between two people. In infancy, contact comfort and trust are important in the development of attachment. Bowlby's ethological theory stresses that the caregiver and the infant are biologically predisposed to form an attachment. Attachment develops in four phases during infancy. Securely attached babies use the caregiver, usually the mother, as a secure base from which to explore the environment.
- Three types of insecure attachment are avoidant, resistant, and disorganized. Ainsworth created the Strange Situation, an observational measure of attachment. Ainsworth notes that secure attachment in the first year of life provides an important foundation for psychological development later in life. The strength of the link between early attachment and later development has varied somewhat across studies.
- Some critics argue that attachment theorists have not given adequate attention to genetics and temperament. Other critics stress that attachment theorists have not adequately taken into account the diversity of social agents and contexts.
- Cultural variations in attachment have been found, but secure attachment is the most common classification in all cultures studied to date. Caregivers of securely attached babies are sensitive to the babies' signals and are consistently available to meet their needs. Caregivers of avoidant babies tend to be unavailable or rejecting. Caregivers of resistant babies tend to be inconsistently available to their babies and usually are not very affectionate. Caregivers of disorganized babies often neglect or physically abuse their babies.
- The mother's primary role when interacting with the infant is caregiving; the father's is playful interaction. More U.S. children are in child care now than at any earlier point in history. The quality of child care in the United States is uneven, and child care remains a

controversial topic. Quality child care can be achieved and seems to have few adverse effects on children. In the NICHD child-care study, infants from low-income families were more likely to receive the lowest quality of care. Also, higher quality of child care was linked with fewer child problems.

- Secure attachment continues to be important throughout the childhood years. Researchers have found that secure attachment to parents in middle and late childhood is linked to lower levels of internalized symptoms, anxiety, and depression.

Adolescence

- Securely attached adolescents show more competent behavior than their insecurely attached counterparts, with the most consistent outcomes involving positive peer relations and emotion regulation. Dating, or thinking about dating, becomes an important aspect of many adolescents' lives. Early dating is associated with developmental problems. Culture can exert a powerful influence on dating.

Adulthood

- Three adult attachment styles are insecure attachment, avoidant attachment, and anxious attachment. Attachment styles in early adulthood are linked with a number of relationship patterns and developmental outcomes. For example, securely attached adults often show more positive relationship patterns than insecurely attached adults. Also, adults with avoidant and anxious attachment styles tend to be more depressed and have more relationship problems than securely attached adults.
- Older adults have fewer attachment relationships than younger adults, and attachment anxiety decreases in older adults.
- Romantic love and affectionate love are two important types of love. Romantic love tends to be more important in early adulthood; affectionate love is more likely to be important in later-life love relationships. Sternberg proposed a triangular theory of love that focuses on different combinations of (1) passion, (2) intimacy, and (3) commitment.

Think about yourself for a few moments. Who are you? What are you like as a person? This chapter seeks to answer such questions by exploring the self, identity, and personality. We will examine these dimensions of people at different points in the life span, from infancy through late adulthood.

1 The Self

LG1 Discuss the main ways the self and understanding others are conceptualized and how they develop.

Self-Understanding and Understanding Others

Self-Esteem and Self-Concept

Self-Regulation

Theorists and researchers who focus on the self usually argue that the self is the central aspect of the individual's personality and that the self lends an integrative dimension to our understanding of different personality characteristics (Robinson & Sedikides, 2021). Several aspects of the self have been studied more than others. These include self-understanding, self-esteem, self-concept, and self-regulation. Let's now turn our attention to how these aspects of the self develop across the life span.

When I say "I," I mean something absolutely unique and not to be confused with any other.

—Ugo Betti
Italian Playwright, 20th Century

SELF-UNDERSTANDING AND UNDERSTANDING OTHERS

What is self-understanding? **Self-understanding** is the cognitive representation of the self, the substance of self-conceptions. For example, an 11-year-old boy understands that he is a student, a boy, a football player, a family member, a video game lover, and a rock music fan. A 13-year-old girl understands that she is a middle school student, a teenager in the midst of puberty, a girl, a soccer player, a student council member, and a movie fan. Self-understanding is based, in part, on roles and membership categories (Harter, 2012, 2013, 2016). It provides the underpinnings for the development of identity. How does self-understanding develop across the life span?

Infancy Studying the self in infancy is difficult mainly because infants cannot tell us how they experience themselves. Infants cannot verbally express their views of the self. They also cannot understand complex instructions from researchers.

A rudimentary form of self-recognition—being attentive and positive toward one's image in a mirror—appears as early as 3 months of age (Mascolo & Fischer, 2007). However, a central, more complete index of self-recognition—the ability to recognize one's physical features—does not emerge until the second year (Thompson, 2006).

One ingenious strategy to test infants' visual self-recognition is the use of a mirror technique in which an infant's mother puts a dot of rouge on the infant's nose and then an observer watches to see how often the infant touches its nose. Next, the infant is placed in front of a mirror, and observers monitor whether nose touching increases. Why does this matter? The idea is that increased nose touching indicates that the infant recognizes the self in the mirror and is trying to touch or rub off the rouge because the rouge violates the infant's view of the self. Increased touching indicates that the infant realizes that it is the self in the mirror but that something is not right since the real self does not have a dot of rouge on it.

Figure 1 displays the results of two investigations that used the mirror technique. The researchers found that before they were 1 year old, infants did not recognize themselves in the mirror (Amsterdam, 1968; Lewis & Brooks-Gunn, 1979). Signs of self-recognition began to appear among some infants when they were 15 to 18 months old. By the time they were 2 years old, most children recognized themselves in the mirror. In sum, infants begin to develop a self-understanding called self-recognition at approximately 18 months of age (Hart & Karmel, 1996).

In one study, researchers conducted biweekly assessments of infant self-recognition from 15 to 23 months of age (Courage, Edison, & Howe, 2004). Self-recognition gradually emerged

self-understanding The individual's cognitive representation of the self, the substance of self-conceptions.

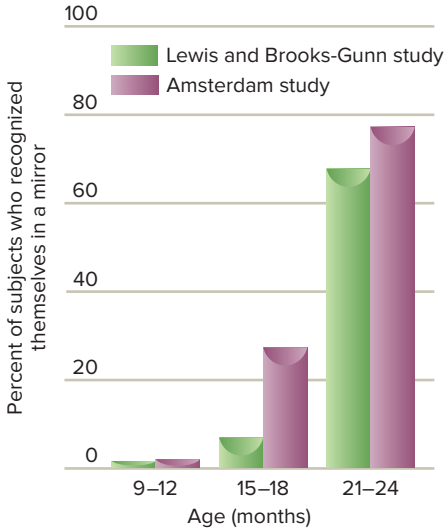

FIGURE **1**

THE DEVELOPMENT OF SELF-RECOGNITION IN INFANCY. The graph shows the findings of two studies in which infants less than 1 year of age did not recognize themselves in the mirror. A slight increase in the percentage of infant self-recognition occurred around 15 to 18 months of age. By 2 years of age, a majority of children recognized themselves. *Why do researchers study whether infants recognize themselves in a mirror?*
Photo: Digital Vision/Getty Images

over this period, first appearing in the form of mirror recognition, followed by use of the personal pronoun "me" and then by recognizing a photo of themselves. These aspects of self-recognition are often referred to as the first indications of toddlers' understanding of the mental state of "me"—"that they are objects in their own mental representation of the world" (Lewis, 2005, p. 363).

Late in the second year and early in the third year, toddlers show other emerging forms of self-awareness that reflect a sense of "me" (Laible & Thompson, 2007). For example, they refer to themselves by saying "Me big"; they label internal experiences such as emotions; they monitor themselves, as when a toddler says, "Do it myself"; and they say that things are theirs (Bullock & Lutkenhaus, 1990; Fasig, 2000). One study revealed that it is not until the second year that infants develop a conscious awareness of their own bodies (Brownell & others, 2009). This developmental change in body awareness marks the beginning of children's representation of their own three-dimensional body shape and appearance, providing an early step in the development of their self-image and identity (Brownell, 2009).

The development of the self in infants and toddlers does not occur in a social vacuum (Thompson, 2015). Interactions with caregivers, older siblings, and others support the development of the self in infants and toddlers. By labeling and describing physical aspects and internal states of infants and toddlers, these persons scaffold infants' and toddlers' self-development and understanding.

Early Childhood

Research studies have revealed that young children are more psychologically aware—of themselves and others—than used to be thought (Thompson, 2015). This *self-awareness* reflects young children's expanding psychological sophistication.

Self-Understanding

Because children can verbally communicate, research on self-understanding in childhood is not limited to visual self-recognition, as it is during infancy (Harter, 2012, 2013, 2016). Mainly through *interviews*, researchers have probed many aspects of children's self-understanding. Here are five main characteristics of self-understanding in young children:

- *Confusion of self, mind, and body*. Young children generally confuse self, mind, and body. Most young children conceive of the self as part of the body, which usually means the head. For them, the self can be described along many material dimensions, such as size, shape, and color.
- *Concrete descriptions*. Preschool children mainly think of themselves and define themselves in concrete terms. A young child might say, "I know my ABC's," "I can count," and "I live in a big house" (Harter, 2006). Although young children mainly describe themselves in terms of concrete, observable features and action tendencies, at about 4 to 5 years of age, as they hear others use psychological trait and emotion terms, they begin to include these in their own self-descriptions (Thompson, 2006). Thus, in a self-description, a 4-year-old might say, "I'm not scared. I'm always happy."
- *Physical descriptions*. Young children also distinguish themselves from others through many physical and material attributes. Says 4-year-old Sandra, "I'm different from Jennifer because I have brown hair and she has blond hair." Says 4-year-old Ralph, "I am different from Hank because I am taller, and I am different from my sister because I have a bicycle."
- *Active descriptions.* The active dimension is a central component of the self in early childhood. For example, preschool children often describe themselves in terms of activities such as play.
- *Unrealistic positive overestimations*. Self-evaluations during early childhood are often unrealistically positive and represent an overestimation of personal attributes (Harter, 2012, 2013, 2016). A young child might say, "I know all of my ABC's" but does not; or might comment, "I'm never scared," which is not the case. These unrealistic positive overestimations of the self occur because young children (1) have difficulty differentiating between their desired and actual competence, (2) cannot yet generate an ideal self that is distinguished from a real self, and (3) rarely engage in *social comparison*—exploring how they compare with others. Young children's self-evaluations also reflect an inability to recognize that they can possess opposite attributes, such as "good" and "bad" or "nice" and "mean" (Harter, 2006).

However, as in virtually all areas of human development, there are individual variations in young children's self-conceptions. In addition, there is increasing evidence that some children

are vulnerable to negative self-attributions (Thompson, 2011). For example, one study revealed that insecurely attached preschool children whose mothers reported a high level of parenting stress and depressive symptoms had a lower self-concept than children in more positive family circumstances (Goodvin & others, 2008). This research indicates that young children's generally optimistic self-ascriptions do not buffer them from adverse, stressful family conditions.

Understanding Others Children also make advances in their understanding of others in infancy and early childhood (Goldwater & others, 2020). As we saw in the chapter on "Information Processing," young children's theory of mind includes understanding that other people have emotions and desires (Gallant, Lavis, & Mahy, 2020). Research indicates that as early as 13 months of age, infants seem to consider another's perspective when predicting their actions (Choi & Luo, 2015).

At about 4 to 5 years, children not only start describing themselves in terms of psychological traits, but they also begin to perceive others in terms of psychological traits. Thus, a 4-year-old might say, "My teacher is nice."

An important part of children's socioemotional development is gaining an understanding that people don't always give accurate reports of their beliefs (Mills & Elashi, 2014). Researchers have found that even 4-year-olds understand that people may make statements that aren't true to obtain what they want or to avoid trouble (Lee & others, 2002). Both the extensive theory of mind research and the recent research on infants' and young children's social understanding underscore that they are not as egocentric as Piaget envisioned (Dahl & Brownell, 2019). Piaget's concept of egocentrism has become so ingrained in people's thinking about young children that too often the current research on social awareness in infancy and early childhood has been overlooked. Research increasingly shows that young children are more socially sensitive and perceptive than was previously envisioned, suggesting that parents and teachers can help them to better understand and interact in the social world by how they interact with them (Thompson, 2012, 2013). If young children are seeking to better understand various mental and emotional states (intentions, goals, feelings, desires) that they know underlie people's actions, then talking with them about these internal states can improve young children's understanding of them (Thompson, 2013).

What characterizes young children's self-understanding?
Tatyana Aleksieva Photography/Getty Images

There is ongoing debate about whether young children are socially sensitive or basically egocentric. Ross Thompson (2012, 2013) comes down on the side of viewing young children as socially sensitive, while Susan Harter (2012, 2013, 2016) argues that there is still evidence to support the conclusion that young children are essentially egocentric.

Whichever side is taken in this debate, it is important to underscore that social interactions and relationships with others contribute significantly to young children's development of the self and understanding of others. In Thompson's (2013) view, "When caregivers exuberantly applaud their child's accomplishments, focus their young child's attention on the consequences of misbehavior, acknowledge shared intentions, work to repair affective mismatches, or talk with their child about emotions, they act as *relational catalysts*, fostering the child's socioemotional growth and helping to refine the child's representations of who they are (and) what other people are like . . ." (p. 113).

Young children are more psychologically aware of themselves and others than used to be thought. Some children are better than others at understanding people's feelings and desires, and to some degree, these individual differences are influenced by conversations caregivers have with young children about feelings and desires.
Don Hammond/DesignPics

Middle and Late Childhood Children's self-understanding becomes more complex during middle and late childhood (Carpendale & Lewis, 2015). And their social understanding, especially in taking the perspective of others, also increases.

Self-Understanding Five key changes characterize the increased complexity of children's self-understanding in middle and late childhood:

- *Psychological characteristics and traits*. In middle and late childhood, especially from 8 to 11 years of age, children increasingly describe themselves in terms of psychological characteristics and traits, in contrast with the more concrete self-descriptions of younger children. Older children are more likely to describe themselves as "*popular, nice, helpful, mean, smart,* and *dumb*" (Harter, 2006, p. 526).
- *Social descriptions*. In middle and late childhood, children begin to include social aspects such as references to social groups in their

What are some changes in children's understanding of others in middle and late childhood?
Asiseeit/E+/Getty Images

self-descriptions (Harter, 2006). For example, a child might describe herself as a Girl Scout, as a Catholic, or as someone who has two close friends.

- *Social comparison*. Children's self-understanding in middle and late childhood includes increasing reference to social comparison (Harter, 2006). That is, elementary-school-age children increasingly think about what they can do in comparison with others.
- *Real self and ideal self*. In middle and late childhood, children begin to distinguish between their real and ideal selves (Harter, 2006). This change involves differentiating their actual competencies from those they aspire to have and think are the most important.
- *Realistic*. In middle and late childhood, children's self-evaluations become more realistic (Harter, 2006). This change may occur because of increased social comparison and perspective taking.

Understanding Others

Perspective taking is the ability to assume another person's perspective and understand his or her thoughts and feelings. Perspective taking is thought to be particularly important in determining whether children will develop prosocial or antisocial attitudes and behavior.

In terms of prosocial behavior, taking another's perspective improves children's likelihood of understanding and sympathizing with others who are distressed or in need. Recent research confirmed that perspective taking underlies children's prosocial actions and that their spontaneous capacity to take others' perspectives develops during the early elementary school years (Sobel & Blankenship, 2021).

In terms of antisocial behavior, recent research indicates that children and adolescents who do not have good perspective-taking skills are more likely to have difficulty in peer relations and to engage in more aggressive and oppositional behavior (Morosan & others, 2017) as well as to be reluctant to give to others (van de Groep, Zanolie, & Crone, 2020).

Executive function is at work in perspective taking (Nilsen & Bacso, 2017). Among the executive functions called on when children engage in perspective taking are cognitive inhibition (controlling one's own thoughts to consider the perspective of others) and cognitive flexibility (seeing situations in different ways).

In middle and late childhood, children become increasingly skeptical of some sources of information about psychological traits. A study of 6- to 9-year-olds revealed that older children were less trusting and more skeptical of others' distorted claims than were younger children (Mills & Elashi, 2014).

Adolescence

The development of self-understanding in adolescence is complex and involves a number of aspects of the self (Harter, 2012). The tendency to compare themselves with others continues to increase in the adolescent years. However, when asked whether they engage in social comparison, most adolescents deny it because they are aware that it is somewhat socially undesirable to do so.

Self-Understanding

Let's examine other ways in which the adolescent's self-understanding differs from the child's:

- *Abstract and idealistic thinking.* According to Piaget's theory of cognitive development, many adolescents begin thinking in more *abstract* and *idealistic* ways. When asked to describe themselves, adolescents are more likely than children to use abstract and idealistic labels. Consider 14-year-old Laurie's abstract description of herself: "I am a human being. I am indecisive. I don't know who I am." Also consider her idealistic description of herself: "I am a naturally sensitive person who really cares about people's feelings. I think I'm pretty good looking."
- *Self-consciousness.* Adolescents are more likely than children to be *self-conscious* and preoccupied with their self-understanding. This self-consciousness and self-preoccupation reflect adolescent egocentrism.
- *Contradictions within the self.* As adolescents begin to differentiate their concept of the self into multiple roles in different relationship contexts, they sense potential contradictions between their differentiated selves (Harter, 2006, 2012). An adolescent might use

perspective taking The ability to assume another person's perspective and understand his or her thoughts and feelings.

this self-description: "I'm moody *and* understanding, ugly *and* attractive, bored *and* inquisitive, caring *and* uncaring, and introverted *and* fun-loving" (Harter, 1986). Young adolescents tend to view these opposing characteristics as contradictory, which can cause internal conflict. However, older adolescents and emerging adults begin to understand that an individual can possess opposing characteristics and to integrate these opposing self-labels into their emerging identity (Harter, 2006, 2012).

- *The fluctuating self.* The adolescent's self-understanding fluctuates across situations and across time (Harter, 2006). The adolescent's self continues to be characterized by instability until the adolescent constructs a more unified theory of self, usually not until late adolescence or even early adulthood.
- *Real and ideal selves.* The adolescent's emerging ability to construct ideal selves in addition to actual ones can be perplexing and agonizing to the adolescent. In one view, an important aspect of the ideal or imagined self is the possible self—what individuals might become, what they would like to become, and what they are afraid of becoming (Markus & Kitayama, 2010, 2012; Markus & Nurius, 1986). Thus, adolescents' **possible selves** include both what adolescents hope to be and what they dread they will become (Aardema & others, 2018; Wainwright, Nee, & Vrij, 2018). The attributes of future positive selves (getting into a good college, being admired, having a successful career) can direct future positive states (Rathbone & others, 2016). The attributes of future negative selves (being unemployed, being lonely, not getting into a good college) can identify what is to be avoided. A study of adolescents in Hong Kong found that those reporting pragmatic support ("If I need to know something about the world, I can ask my parents," for example) had possible selves that were focused more on career and school, and they were more likely to think they could attain their hoped-for possible selves and avoid their feared possible selves (Zhu & others, 2014).
- *Self-integration.* In late adolescence and emerging adulthood, self-understanding becomes more integrative, with the disparate parts of the self more systematically pieced together (Harter, 2006, 2012, 2013). Older adolescents and emerging adults are more likely to detect inconsistencies in their earlier self-descriptions as they attempt to construct a general theory of self and an integrated sense of identity.

How does self-understanding change in adolescence?
Image Source/Getty Images

Understanding Others

Of course, becoming a competent adolescent involves not only understanding oneself but also understanding others. Among the aspects of understanding others that are important in adolescent development are perceiving others' traits, understanding multiple perspectives, and monitoring their social world.

As adolescence proceeds, teenagers develop a more sophisticated understanding of others. They come to understand that other people are complex and have public and private faces (Harter, 2006, 2012).

According to Robert Selman (1980), developmental changes in perspective taking begin with the egocentric viewpoint in early childhood and end with in-depth perspective taking in adolescence.

In the chapter titled "Information Processing," you read that an important cognitive activity in metacognition is cognitive monitoring, which can also be very helpful in social situations (Bellon, Fias, & Smedt, 2020). As part of their increased awareness of themselves and others, adolescents monitor their social world more extensively than they did when they were children. Adolescents engage in a number of social cognitive monitoring activities on virtually a daily basis. For example, an adolescent might think, "I would like to get to know this guy better, but he is not very open. Maybe I can talk to some other students about what he is like." Another adolescent might check incoming information about a club or a clique to determine if it is consistent with her impressions of the club or clique. Yet another adolescent might question someone or paraphrase what the person has just said about her feelings to make sure that he has accurately understood them. Adolescents' ability to monitor their social world may be an important aspect of their social maturity (Flavell, 1979).

What are some important aspects of social understanding in adolescence?
SW Productions/Getty Images

Adulthood

As individuals move into the traditional college-age years and make the transition from adolescence to adulthood, they begin to engage in more self-reflection about what they want to do with their lives. The extended schooling that takes place in developed countries like the United States and Japan provides time for further self-reflection and self-understanding.

possible selves What adolescents hope to become as well as what they dread they might become.

The living self has one purpose only: to come into its own fullness of being, as a tree comes into full blossom, or a bird into spring beauty, or a tiger into luster.

–D. H. Lawrence
English Author, 20th Century

Self-Awareness An aspect of self-understanding that becomes especially important in early adulthood is *self-awareness*—that is, the degree to which a young adult is aware of his or her psychological makeup, including strengths and weaknesses. Many individuals do not have very good awareness of their psychological makeup and skills, as well as the causes of their weaknesses (Hull, 2012). For example, how aware is the person that she or he is a good or bad listener, uses the best strategies to solve personal problems, and is assertive rather than aggressive or passive in resolving conflicts? Awareness of strengths and weaknesses in these and many other aspects of life is an important dimension of self-understanding throughout the adult years, and early adulthood is a time when individuals can benefit considerably from addressing some of their weaknesses.

Possible Selves Another aspect of self-understanding that is important during adulthood involves possible selves (Beck & Jackson, 2020). Recall that possible selves are what individuals might become, what they would like to become, and what they are afraid of becoming (Frazier, Schwartz, & Metcalfe, 2021). Adults in their twenties mention many possible selves that they would like to become and might become. Some of these are unrealistic, such as being happy all of the time and being very rich. As individuals get older, they often describe fewer possible selves and portray them in more concrete and realistic ways. By middle age, individuals frequently describe their possible selves in terms of areas of their life in which they already have performed, such as "being good at my work" or "having a good marriage" (Cross & Markus, 1991). Also, when some individuals are middle-aged adults, their possible selves center on attaining hoped-for selves, such as acquiring material possessions, but when they become older adults, they are more concerned with maintaining capabilities that they have attained and preventing or avoiding health problems and dependency (Smith, 2009).

What characterizes self-awareness and possible selves in young adults?
wavebreakmedia/Shutterstock

Many individuals continue to revise their possible selves as they go through the adult years (Croft, Schmader, & Block, 2019). This ability to revise possible selves and adapt them to find a better match between desired and achieved goals may be an important aspect of maintaining positive self-esteem and psychological well-being as individuals get older (Bengtson, Reedy, & Gordon, 1985).

Life Review Another important aspect of self-understanding in adulthood is the *life review*. Life review is prominent in Erikson's final stage of psychosocial development, which is integrity versus despair. Life review involves looking back at one's life experiences, evaluating them, interpreting them, and often reinterpreting them (Liu & Li, 2021; Rose & others, 2020). As the past marches in review, the older adult surveys it, observes it, and reflects on it. Reconsideration of previous experiences and their meaning occurs, often with revision or expanded understanding taking place. This reorganization of the past may provide a more valid picture for the individual, bringing new and significant meaning to one's life. It may also help prepare the individual for death and in the process reduce fear (Rubin, Parrish, & Miyawaki, 2019).

One aspect of life review involves identifying and reflecting on not only the positive aspects of one's life but also on regrets as part of developing a mature wisdom and self-understanding (Korte & others, 2014). The hope is that by examining not only the positive aspects of one's life but also what an individual has regretted doing, a more accurate vision of the complexity of one's life and possibly increased life satisfaction will be attained (King & Hicks, 2007).

What characterizes a life review in late adulthood?
Corbis/VCG/Getty Images

Although thinking about regrets can be helpful as part of a life review, research indicates that it is important for older adults to not dwell on regrets, especially since opportunities to undo regrettable actions decline with age (Suri & Gross, 2012). One study revealed that an important characteristic of older adults who showed a higher level of emotion regulation and successful aging was reduced responsiveness to regrets (Brassen & others, 2012).

Some clinicians use *reminiscence therapy* with their older clients, which involves discussing past activities and experiences with another individual or group (Ching-Teng & others, 2020). The therapy may include the use of photographs, familiar items, and video/audio recordings. Researchers have found that reminiscence therapy improves the mood and quality of life of older adults, including those with dementia (Cuevas & others, 2020; Zhao,

2021). In a recent research review of older adults, reminiscence therapy was linked to a decline in depressive and anxiety symptoms, improved life satisfaction, and increased social engagement (Shropshire, 2020). Also, a recent study found that reminiscence therapy reduced the cognitive impairment, anxiety, and depression of post-stroke patients (Cheng & others, 2021). Further, another recent study indicated that reminiscence therapy improved the cognition and quality of life of Alzheimer disease patients (Perez-Saez & others, 2021). Successful aging, though, doesn't mean thinking about the past all of the time. In one study, older adults who were obsessed about the past were not as well adjusted as older adults who integrated their past and present (Wong & Watt, 1991).

How is self-esteem related to school performance?
Fuse/Getty Images

SELF-ESTEEM AND SELF-CONCEPT

High self-esteem and a positive self-concept are important characteristics of children's and adults' well-being (de Moor & others, 2021; Twenge & Campbell, 2020). **Self-esteem** refers to global evaluations of the self. Self-esteem is also referred to as *self-worth* or *self-image*. For example, a person may perceive that she or he is not merely a person but a *good* person. Of course, not all people have an overall positive image of themselves. **Self-concept** refers to domain-specific evaluations of the self (Ramirez-Granizo & others, 2020). Individuals can make self-evaluations in many domains of their lives—academic, athletic, appearance, and so on. In sum, *self-esteem* refers to global self-evaluations, *self-concept* to domain-specific evaluations (Harter, 2006, 2012). Investigators sometimes use the terms *self-esteem* and *self-concept* interchangeably and don't always precisely define them. However, the distinction between self-esteem as global self-evaluation and self-concept as domain-specific self-evaluation should help you keep the terms straight. The foundations of self-esteem and self-concept emerge from the quality of parent-child interaction in infancy, childhood, and adolescence (Lee & Simpkins, 2021). Children with high self-esteem are more likely to be securely attached to their parents and to have parents who engage in sensitive caregiving (Verschueren, 2020). In a longitudinal study, the quality of children's home environment (which involved assessment of parenting quality, cognitive stimulation, and the physical home environment) was linked to their self-esteem in early adulthood (Orth, 2017). Also, a recent study conducted in Brazil, Portugal, and Spain found that parental warmth was a key factor in adolescent self-esteem in all three countries (Martinez & others, 2020). And in another recent study, maternal warmth, monitoring, low maternal depression, economic well-being, and father presence were linked to higher self-esteem in children and adolescents (Krauss, Orth, & Robins, 2020).

Issues in Self-Esteem

What are the consequences of low self-esteem? For many children, adolescents, and adults, the emotional discomfort of low self-esteem is only temporary, but for some, low self-esteem can develop into other problems. Low self-esteem has been implicated in overweight and obesity (Gow & others, 2020), anxiety and depression (Sahlan & others, 2021), suicide (Reid-Russell & others, 2021), delinquency (Gauthier-Duchesne, Hebert, & Blais, 2021), and better sexual health (Sakaluk & others, 2020).

Is self-esteem related to performance in school or on the job? There are "only modest correlations between school performance and self-esteem, and these correlations do not indicate that high self-esteem causes good performance" (Baumeister & others, 2003, p. 1). Attempts to increase students' self-esteem have not produced improvements in academic performance (Davies & Brember, 1999).

In some studies, adult job performance is linked to self-esteem, but the correlations vary greatly and the direction of the causation is not clear (Baumeister & others, 2003). Occupational success might lead to higher self-esteem, but people with high self-esteem also might be more likely to succeed than people with moderate or low self-esteem.

Is self-esteem related to happiness? Self-esteem is strongly related to happiness, and it seems likely that high self-esteem increases happiness, whereas low self-esteem reduces it (Stadelmann & others, 2017).

Is self-esteem related to physical appearance? Self-esteem is related to perceived physical appearance. For example, researchers have found that in adolescence, global self-esteem is correlated more strongly with physical appearance than with scholastic competence, social acceptance, behavioral conduct, and athletic competence (Harter, 1999) (see Figure 2). This association between perceived physical appearance and self-esteem is not confined to adolescence but continues across the life span from early childhood through middle age (Harter, 1999, 2006).

self-esteem The global evaluative dimension of the self. Self-esteem is also referred to as self-worth or self-image.

self-concept Domain-specific evaluations of the self.

Domain	Harter's U.S. Samples	Other Countries
Physical appearance	.65	.62
Scholastic competence	.48	.41
Social acceptance	.46	.40
Behavioral conduct	.45	.45
Athletic competence	.33	.30

FIGURE 2

CORRELATIONS BETWEEN GLOBAL SELF-ESTEEM AND DOMAINS OF COMPETENCE. *Note*: The correlations shown are the average correlations computed across a number of studies. The other countries in this evaluation were England, Ireland, Australia, Canada, Germany, Italy, Greece, the Netherlands, and Japan. Correlation coefficients can range from –1.00 to +1.00. The correlations between physical appearance and global self-esteem (.65 and .62) are moderately high.

Does self-esteem in adolescence foreshadow adjustment and competence in adulthood? A New Zealand longitudinal study assessed self-esteem at 11, 13, and 15 years of age and adjustment and competence of the same individuals when they were 26 years old (Trzesniewski & others, 2006). The results revealed that adults characterized by poorer mental and physical health, worse economic prospects, and higher levels of criminal behavior were more likely to have had low self-esteem in adolescence than their better-adjusted, more competent adult counterparts. And in another longitudinal investigation that monitored individuals from early adolescence through emerging adulthood, high self-esteem in adolescence was linked to more long-term personal goals, better self-rated physical health, and fewer depressive symptoms in emerging adulthood (Arsandaux, Galera, & Salamon, 2021).

An important point needs to be made about much of the research on self-esteem: It is correlational rather than experimental. Correlation does not equal causation. Thus, if a correlational study finds an association between low self-esteem and depression, it could be equally likely that depression causes low self-esteem or that low self-esteem causes depression. Also, unmeasured third variables might account for an apparent correlation (for example, both depression and low self-esteem might be jointly caused by family conflict). A longitudinal study explored whether self-esteem is a cause or consequence of social support in youth (Marshall & others, 2014). In this study, self-esteem predicted subsequent changes in social support, but social support did not predict subsequent changes in self-esteem. However, in a longitudinal study with Mexican-origin youth, a reciprocal relation between self-esteem and achievement was found (Zheng & others, 2020).

The living self has one purpose only: to come into its own fullness, as a tree comes into full blossom, or a bird into spring beauty, or a tiger into luster.

–D.H. Lawrence
British Author, 20th Century

Self-Esteem: Perception and Reality Self-esteem reflects perceptions that do not always match reality (Derry, Chan, & Bayliss, 2020; Weiss & others, 2021). An adolescent's or adult's self-esteem might indicate a perception about whether he or she is intelligent and attractive, for example, but that perception may not be accurate. Thus, high self-esteem may refer to accurate, justified perceptions of one's worth as a person and one's successes and accomplishments, but it can also indicate an arrogant, grandiose, unwarranted sense of superiority over others. In the same manner, low self-esteem may suggest either an accurate perception of one's shortcomings or a distorted, even pathological sense of insecurity and inferiority.

Narcissism refers to a self-centered and self-concerned approach toward others. Typically, narcissists are unaware of their actual self and how others perceive them. This lack of awareness contributes to their adjustment problems. Narcissists are excessively self-centered and self-congratulatory, viewing their own needs and desires as paramount. As a result, narcissists rarely show any empathy toward others. In fact, narcissists often devalue people around them to protect their own precarious self-esteem, yet they often respond with rage and shame when others do not admire them or treat them in accordance with their grandiose fantasies about themselves. Narcissists are at their most grandiose when their self-esteem is threatened. They may fly into a frenzy if they have given an unsatisfactory performance.

What are two common forms of narcissism?
Westend61/Getty Images

narcissism A self-centered and self-concerned approach toward others.

So far, narcissism has been portrayed as a general trait. However, there have been an increasing number of efforts to describe different types of narcissism (Donnellan, Ackerman, & Wright, 2021). One of the most common distinctions has been made been between vulnerable and grandiose narcissism. *Vulnerable narcissism* is characterized by excessive self-absorption, introversion, and insecurity. *Grandiose narcissism* is characterized by an exaggerated sense of superiority, extraversion, and domineering behavior. In a recent study, grandiose narcissism was related to having higher life satisfaction and was also associated with being inauthentic (Kaufman & others, 2020). Also, in a recent study of Chinese adolescents, whether or not narcissism was linked to mental health problems depended on levels of self-esteem–adolescents with high narcissism and high self-esteem had positive mental health outcomes, while those with high narcissism and low self-esteem had problematic mental health outcomes (Xu, Huebner, & Tian, 2020).

Are today's adolescents and emerging adults more self-centered and narcissistic than their counterparts in earlier generations? Research by Jean Twenge and her colleagues (2008a, b) indicated that compared with baby boomers who were surveyed in 1975, twelfth-graders surveyed in 2006 were more self-satisfied overall and far more confident that they would be very good employees, mates, and parents. Today's adolescents are sometimes labeled "Generation Me." However, other large-scale analyses have revealed no increase in high school and college students' narcissism from 1976 through 2006 (Trzesniewski, Donnellan, & Robins, 2008). In sum, the extent to which recent generations of adolescents have higher self-esteem and are more narcissistic than earlier generations is controversial (Donnellan & Trzesniewski, 2010; Twenge, Carter, & Campbell, 2017).

Developmental Changes Self-esteem fluctuates across the life span (Reitz & others, 2020). One cross-sectional study assessed the self-esteem of a very large, diverse sample of 326,641 individuals ranging from 9 to 90 years of age (Robins & others, 2002). About two-thirds of the participants were from the United States. The individuals were asked to respond to the statement "I have high self-esteem" on a scale from 1 to 5, with 1 meaning "strongly agree" and 5 meaning "strongly disagree." This research focused on both developmental changes and gender differences. Self-esteem decreased in adolescence, increased in the twenties, leveled off in the thirties, rose in the fifties and sixties, and then dropped in the seventies and eighties (see Figure 3). In most age periods, the self-esteem of males was higher than the self-esteem of females. Also, in a recent study of individuals in the second half of life, self-esteem peaked at 50 years of age and declined thereafter (von Soest & others, 2018). Let's now explore developmental changes in self-esteem in more detail.

Childhood and Adolescence Researchers have found that the accuracy of self-evaluations increases across the elementary school years (Harter, 2006, 2012, 2016). Young children tend to provide inflated views of themselves, but by about 8 years of age most children give more realistic appraisals of their skills (Harter, 2006). For example, older elementary school children who report a positive self-image of their performance in sports indeed are the ones who are reported by peers to be good at athletics.

Adolescents in general have long been described as having low self-esteem (Robins & others, 2002). However, the majority of adolescents actually have a positive self-image. In an extensive cross-cultural study, Daniel Offer and his colleagues (1988) sampled the self-images of adolescents around the world—in the United States, Australia, Bangladesh, Hungary, Israel, Italy, Japan, Taiwan, Turkey, and West Germany. Almost three-fourths of the adolescents had a healthy self-image. Also, a recent meta-analysis concluded that the findings do not support the notion that self-evaluations reach a critical low point in many domains in early adolescence (Orth & others, 2021).

Some researchers note that gender differences in self-esteem emerge by early adolescence, and these were found in the study just described (Robins & others, 2002). Girls and boys enter first grade with roughly equivalent levels of self-esteem. Yet some research studies have shown that by the middle school years girls' self-esteem is significantly lower than boys' (American

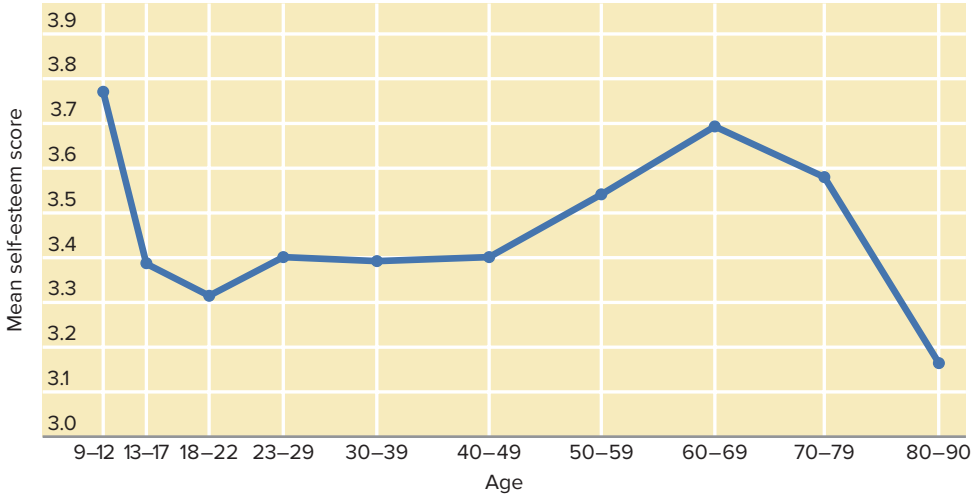

FIGURE **3**

SELF-ESTEEM ACROSS THE LIFE SPAN. One cross-sectional study found that self-esteem was high in childhood, dropped in adolescence, increased through early and middle adulthood, then dropped in the seventies and eighties (Robins & others, 2002). More than 300,000 individuals were asked the extent to which they have high self-esteem on a 5-point scale, with 5 being "Strongly Agree" and 1 being "Strongly Disagree."

Association of University Women, 1992). For example, one study confirmed that male adolescents had higher self-esteem than female adolescents did (McLean & Breen, 2009).

However, other researchers caution that the self-esteem of girls is only slightly lower than boys' and still in the positive range (Harter, 2013, 2016; Kling & others, 1999). Researchers also have found that after age 13, girls' self-esteem increases through the remainder of adolescence and in emerging adulthood (Baldwin & Hoffman, 2002).

A current concern is that too many of today's college students grew up receiving empty praise and as a consequence have inflated self-esteem (Graham, 2005; Stipek, 2005). Too often they were given praise for performance that was mediocre or even poor. When they are in college, they may have difficulty handling competition and criticism. The title of a book, *Dumbing Down Our Kids: Why American Children Feel Good About Themselves But Can't Read, Write, or Add* (Sykes, 1995), vividly captures the theme that many U.S. children's academic problems stem from receiving unmerited praise as part of an effort to prop up their self-esteem. In a series of studies, researchers found that inflated praise, although well intended, may cause children with low self-esteem to avoid important learning experiences such as tackling challenging tasks (Brummelman & others, 2014). And one study found that narcissistic parents especially overvalue their children's talents (Brummelman & others, 2015).

Even when older adults have physical problems, other aspects of their lives, such as spending time with people whose company they enjoy, can help to buffer any decline in their self-esteem.
Westend61/Getty Images

Adulthood Are there differences in the self-esteem of young, middle-aged, and older adults? In the self-esteem study described earlier, self-esteem dropped in late adulthood (Robins & others, 2002). However, some researchers have not found any differences in self-esteem across the age periods of adulthood (McGue, Hirsch, & Lykken, 1993).

Given that older adults have more physical problems, why wouldn't they have lower self-esteem than young or middle-aged adults? One possible reason is that many older adults don't interpret their "losses" as negatively, and don't become as emotionally upset, as younger adults would (Carstensen & Freund, 1994). For example, being asked to retire at age 63 may not be nearly as devastating as being fired from a job at 40. Furthermore, Laura Carstensen (2019) argues that knowledge-related goals decrease in older adults, whereas emotion-related goals increase. And many older adults are able to reach their emotion-related goals of honing their social network to spend most of their time with the people with whom they have enjoyed satisfying close relationships in the past (Carstensen, 2019).

Why might self-esteem decline for some older adults? Explanations include deteriorating physical health and negative societal attitudes toward older adults, although these factors were not examined in the large-scale study just described. Researchers have found that in late adulthood, being widowed, institutionalized, or physically impaired, having a low religious commitment, and experiencing a decline in health are linked to low self-esteem (Giarrusso & Bengtson, 2007).

Strategies for Increasing Self-Esteem What are some good strategies for increasing self-esteem? Five ways to improve self-esteem are (1) identify the causes of low self-esteem and the domains of competence important to the self; (2) provide emotional support and opportunities for social approval; (3) take responsibility for one's own self-esteem; (4) achieve goals; and (5) develop effective coping strategies.

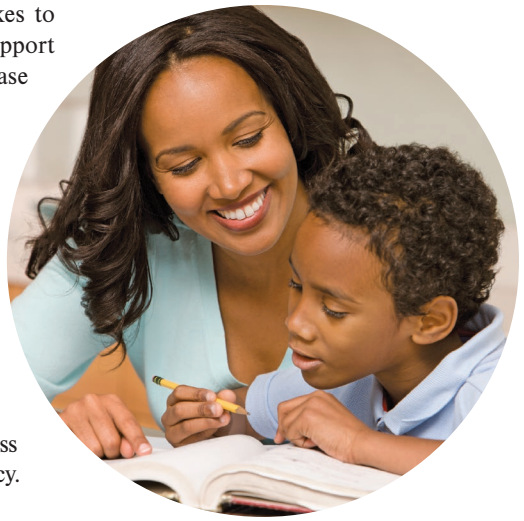
Identifying sources of self-esteem—that is, competence in domains important to the self—is critical to improving self-esteem (Harter, 2012, 2016). Susan Harter (1990) points out that the self-esteem enhancement programs of the 1970s and 1980s, in which self-esteem itself was the target and individuals were encouraged to simply feel good about themselves, were ineffective. Rather, Harter notes that intervention must occur at the level of the *causes* of self-esteem if the individual's self-esteem is to improve significantly. Individuals have the highest self-esteem when they perform competently in domains that are important to them. Therefore, people should be encouraged to identify and value areas of competence.

Emotional support and social approval also powerfully influence self-esteem. Some children with low self-esteem come from conflicted families or conditions in which they experienced abuse or neglect—situations in which support was unavailable. In some cases, alternative sources of support can be implemented either informally through the encouragement of a teacher, a coach, or another significant adult, or more formally through programs such as Big Brothers and Big Sisters. As peer approval becomes increasingly important during adolescence, peer support is an important influence on the adolescent's self-esteem.

Developing self-confidence and believing that one has the ability to do what it takes to improve self-esteem are other good strategies. Although it is helpful to have the social support and emotional approval of others, it is also very important to take the initiative to increase one's own self-esteem.

Achievement can also improve an individual's self-esteem (Baumeister, 2013). For example, self-esteem can be enhanced by the straightforward teaching of skills to individuals. People develop higher self-esteem when they know how to carry out the important tasks to accomplish goals and they realize that by carrying out these tasks they are more likely to reach their goals.

Self-esteem often increases when individuals face a problem and try to cope with it rather than avoid it (Mash & Wolfe, 2019). When coping prevails, the individual often faces problems realistically, honestly, and nondefensively. This process leads to favorable self-evaluative thoughts, which then lead to self-generated approval and higher self-esteem. The opposite is true of low self-esteem. Unfavorable self-evaluations trigger denial, deception, and avoidance in an attempt to disavow that which has already been glimpsed as true. This process leads to self-generated disapproval as a form of feedback to the self about personal inadequacy.



How can parents help children develop higher self-esteem?

SELF-REGULATION

Self-regulation involves the ability to control one's behavior without having to rely on others' help. Self-regulation includes the self-generation and cognitive monitoring of thoughts, feelings, and behaviors in order to reach a goal (Carver & Scheier, 2021; Inzlicht & others, 2021). An individual might develop better self-control in one domain of life (physical, cognitive, or socio-emotional) but not in the other domains.

Throughout most of the life span, individuals who engage in self-regulation are better achievers and are more satisfied with their lives than their counterparts who let external factors dominate their lives (Schunk, 2020). For example, researchers have found that, compared with low-achieving students, high-achieving students engage in greater self-regulation. They do this by setting more specific learning goals, using more strategies to learn and adapt, self-monitoring more, and more systematically evaluating their progress toward a goal (Alt & Naamati-Schneider, 2021; McClelland, Cameron, & Alonso, 2019).

Infancy and Early Childhood

In the chapter "Emotional Development and Attachment" we discussed the importance of children learning to regulate their emotions as they develop. Emotion regulation is an important aspect of the overall development of self-regulation (Dollar & Calkins, 2020). How do other aspects of self-regulation develop? Claire Kopp (1982, 1987, 2008) described a developmental process that begins early in life. Initially, beginning at about 12 to 18 months of age, infants depend completely on their caregivers for reminder signals about acceptable behaviors. At this age, infants begin to show compliance with caregivers' demands. For example, a parent might say, "No. Don't touch!" and the infant doesn't touch the forbidden object.

The next phase of developing self-regulation takes place at approximately 2 to 3 years of age. At this point, children begin to comply with the caregiver's expectations in the absence of external monitoring by the caregiver. Thus, most 2- to 3-year-old children are aware of where they may and may not play and which objects they may and may not touch if they are at home, on a playground, or in the homes of friends and relatives.

Nonetheless, at these young ages, there are clear limitations on self-regulation (Thompson, 2015). Given a strong stimulus, such as a ball rolling down the street or the motivation to explore an interesting place, toddlers often ignore safety and disregard exhortations. Also, only rudimentary aspects of delaying gratification are present at these early ages. For example, when 2-year-olds are confronted with an unexpected delay (such as not being able to go outside and play), they often whine and beg to engage in the activity. But there are clear signs of advances in self-initiated regulation, as when young children announce a toy cleanup without prompting from caregivers.

Preschoolers become better at self-control, learning how to resist temptation and giving themselves instructions that keep them focused (McClelland & Cameron, 2019). Thus, toward the end of the preschool years, children might say to themselves, "No. I can't do that. I'm working," in response to a temptation to stop working and do something else, like play with an attractive toy.

Recent research confirms the importance of developing good self-control in early childhood as well as the role of parenting in the development of self-control (Spinrad, Morris, &

self-regulation The ability to control one's behavior without having to rely on others for help.

Luthar, 2020). For example, in one study, low self-regulation in early childhood was linked to a higher level of externalizing problems in adolescence (Perry & others, 2018a). In further research, overcontrolling parenting at 2 years of age was related to lower emotion regulation at 5 years of age, which in turn was associated with emotional and school problems at age 10 (Perry & others, 2018b). In addition, a recent study indicated that positive maternal and paternal parenting (positive mood, good communication skills, and being assertive) were linked to young children's effortful control (Neppl & others, 2020). And another recent study indicated that the majority of 4- and 5-year-olds were developmentally on track with self-regulation (Claussen & others, 2021). However, compared with children who were described as not on track, those on track lived in financially and socially advantaged environments and were less likely to have been exposed to family adversity.

Middle/Late Childhood and Adolescence One of the most important aspects of the self in middle and late childhood is an increased capacity for self-regulation (Schunk, 2020). This increased capacity is characterized by deliberate efforts to manage one's behavior, emotions, and thoughts that lead to increased social competence and achievement. In one study, higher levels of self-control assessed at 4 years of age were linked to improvements in the math and reading achievement of early-elementary-school children living in predominantly rural and low-income contexts (Blair & others, 2015). Also, in a recent meta-analytic review, low self-regulation at 8 years of age was linked to externalizing problems, depressive symptoms, obesity, cigarette smoking, and illicit drug use at 13 years of age (Robson, Allen, & Howard, 2020). Further, a longitudinal study found that a higher level of self-control in childhood was linked to a slower pace of aging (assessed with 18 biomarkers—cardiovascular and immune system, for example) at 26, 32, and 38 years of age (Belsky & others, 2017). And another longitudinal study that followed individuals from birth to 45 years of age revealed that those who had shown better self-control in childhood aged more slowly in their bodies and showed fewer signs of aging in their brains during adulthood (Richmond-Raker & others, 2021). Also in this study, in middle age these individuals were better equipped to handle later-life health, financial, and social demands.

The increased capacity for self-regulation is linked to developmental advances in the brain's prefrontal cortex (Palacios-Barrios & Hanson, 2019). Increased focal activation in the prefrontal cortex is linked to improved cognitive control. Such cognitive control includes self-regulation (Blair, Raver, & Finegood, 2016).

How might self-regulation develop in adolescence? On the one hand, advances in cognitive skills (logical thinking, for example), increased introspection, and the greater independence of adolescence might lead to increased self-control. Also, advances in cognitive abilities provide adolescents with a better understanding of the importance of delaying gratification in exchange for something desirable (such as a good grade in a class) rather than seeking immediate gratification (listening to music rather than studying). On the other hand, factors such as an increased sense of invincibility (which can lead to risk taking and sensation seeking), impulsiveness, and social comparison might reduce self-control in this age group. In a recent study of more than 5,000 individuals from 10 to 30 years of age in 11 countries in Africa, Asia, Europe, and the Americas, sensation seeking increased steadily from 11 years of age through late adolescence, peaking at 19 years of age and declining through the twenties (Steinberg & others, 2018). However, in this study, self-regulation increased steadily from 11 years of age into emerging adulthood, reaching a plateau at 23 to 26 years of age.

How does self-regulation change during childhood and adolescence?
Roy Botterell/Fuse/Getty Images

As we indicated in the chapter on "Physical Development and Biological Aging," developmental changes in the brain are linked to self-regulation (Casey & others, 2019). Recall that the limbic system, which includes the amygdala, develops much earlier in adolescence and is associated with an increase in emotional intensity and mood swings, as well as increases in sensation seeking and risk taking. However, the prefrontal cortex, which is at a higher level in the brain, continues to develop well into the emerging adult years and is the seat of self-regulation. Thus, during adolescence, the prefrontal cortex has not developed sufficiently to rein in the powerful emotions and passions connected with the limbic system's development.

Self-regulation is important in many aspects of adolescents' lives, including academic achievement, developing good health habits, not engaging in risky sexual behavior, and not binge drinking. For example, a recent study of middle school students indicated that self-control was a key factor in developing good health habits (Kang & You, 2018). Also, a recent study indicated that for 13- to 16-year-olds, females reported having a higher level of self-control and self-monitoring than did their male counterparts (Tetering & others, 2020).

A key component of self-regulation is engaging in *effortful control*, which involves inhibiting impulses and not engaging in destructive behavior, focusing and maintaining attention despite distractions, and initiating and completing tasks that have long-term value, even if they may seem unpleasant (Lunetti & others, 2021). One study found that effortful control at 17 years of age predicted academic persistence and educational attainment at 23 to 25 years of age (Veronneau & others, 2014). In this study, effortful control was just as strong a predictor of educational attainment as were past grade point averages and parents' educational levels. And in a study of Mexican-origin families, adolescents who experienced more hostility from their parents, associated more with deviant peers, lived in more violent neighborhoods, and encountered more ethnic discrimination were characterized by lower levels of effortful control (Atherton, Lawson, & Robins, 2020). Also in this study, adolescents whose parents closely monitored their behavior and whereabouts showed a smaller decline in effortful control.

Some researchers emphasize the early development of self-regulation in childhood and adolescence as a key contributor to adult health and even longevity (Vink & others, 2020). For example, Nancy Eisenberg and her colleagues (2014) concluded that research indicates self-regulation fosters conscientiousness later in life, both directly and through its link to academic motivation/success and internalized compliance with norms.

selective optimization with compensation theory The theory that successful aging involves three strategies: selection, optimization, and compensation.

developmental **connection**
Information Processing
Cognitive control (inhibition and flexibility) increases from childhood through early adulthood. Connect to "Information Processing."

Adulthood

Self-control plays an important role in adult development (Dixon & Lachman, 2019). For example, higher levels of self-control are linked to better health and adjustment (Bercovitz, Ngnoumen, & Langer, 2019).

Self-control increases in early and middle adulthood (Agrigoroaei & others, 2019). Researchers have found a decline in perceived self-control of health and cognitive functioning in older adults (Bertrand, Graham, & Lachman, 2013).

Although older adults are aware of age-related losses, most still effectively maintain a sense of self-control. Recent research indicates that self-control plays an important role in older adults' quality of life, including lower levels of depression and obesity (Bercovitz, Ngnoumen, & Langer, 2019). Also, in a recent study, older adults who had a higher daily level of self-control perceived themselves to be younger (Bellingtier & Neupert, 2019).

Selective optimization with compensation theory states that successful aging is linked with three main factors: selection, optimization, and compensation (SOC). The theory states that individuals can produce new resources and allocate them effectively to tasks they want to master (Baltes & Smith, 2008; Nikitin & Freund, 2019). Selection, optimization, and compensation can be described as follows:

- *Selection* is based on the concept that older adults have a reduced capacity and a loss of functioning, which require a reduction in performance in most life domains such as memory and physical skills.
- *Optimization* suggests that it is possible to maintain performance in some areas through continued practice and the use of new technologies. Examples might include doing crossword puzzles to maintain memory skills and exercising to optimize strength.
- *Compensation* becomes relevant when life tasks require a level of capacity beyond the current level of the older adult's performance potential. Older adults especially need to compensate in circumstances that impose high mental or physical demands, such as when thinking about and memorizing new material very rapidly, reacting quickly when driving a car, or running fast. When older adults develop an illness, the need for compensation increases.

According to selective optimization with compensation theory, what characterizes successful aging?

connecting development to life

Strategies for Effectively Engaging in Selective Optimization with Compensation

What are some good strategies that aging adults can use to attain selective optimization with compensation? According to Paul Baltes and his colleagues (Baltes, Lindenberger, & Staudinger, 2006; Freund & Baltes, 2002), the following strategies are likely to be effective:

Selection Strategies

- **Focus on the most important goal at a particular time.**
- **Think about what you want in life, and commit yourself to one or two major goals.**
- **Realize that to reach a particular goal, you may need to abandon other goals.**

Optimization Strategies

- **Keep working on what you have planned until you are successful.**
- **Persevere until you reach your goal.**
- **When you want to achieve something, understand that you may need to wait until the right moment arrives.**

Compensation

- **When things don't go the way they used to, search for other ways to achieve what you want.**
- **If things don't go well for you, be willing to let others help you.**
- **When things don't go as well as in the past, keep trying other ways until you can achieve results that are similar to what you accomplished earlier in your life.**

Which of the selection, optimization, and compensation strategies have you used? Which of the strategies would you benefit from using more?

Selective optimization with compensation theory was proposed by Paul Baltes and his colleagues (Baltes, 2003; Baltes, Lindenberger, & Staudinger, 2006). They described the life of the pianist Arthur Rubinstein (1887–1982) to illustrate their theory. When he was interviewed at 80 years of age, Rubinstein said that three factors were responsible for his ability to maintain his status as an admired concert pianist into old age. First, he mastered the weakness of old age by reducing the scope of his performances and playing fewer pieces (which reflects selection). Second, he spent more time at practice than he had spent earlier in his life (which reflects optimization). Third, he used special strategies, such as slowing down before fast segments, thus creating the illusion of faster playing (which reflects compensation).

The process of selective optimization with compensation is likely to be effective whenever people pursue successful outcomes (Joly-Burra, Van der Linden, & Ghisletta, 2020; Zhang & others, 2021). In a study of individuals from 22 to 94 years of age, middle-aged and older adults, as well as individuals who were less healthy, reported higher levels of happiness on days when they used more selective optimization with compensation strategies (Teshale & Lachman, 2016). Also, a recent study found that SOC strategies improved job performance of adults when they were faced with intense job demands (Mauno & others, 2020). And a recent study revealed that SOC strategies were linked to successful aging in Korean women (Han & Ko, 2021).

What makes SOC attractive to researchers in aging is that it makes explicit how individuals can manage and adapt to losses (Nikitin & Freund, 2019). By using SOC, they can continue to lead satisfying lives, although in a more restricted manner. Loss is a common dimension of old age, although there are wide variations in the nature of the losses involved. Because of these individual variations, the specific forms of selection, optimization, and compensation used will likely vary depending on the person's life history, pattern of interests, values, health, skills, and resources. To read about some strategies for effectively engaging in selective optimization with compensation, see the *Connecting Development to Life* interlude.

In Baltes' view (Baltes & Smith, 2008), the selection of domains and life priorities is an important aspect of development. Life goals and priorities likely vary across the life course for most people. For many individuals, it is not just the sheer attainment of goals, but rather

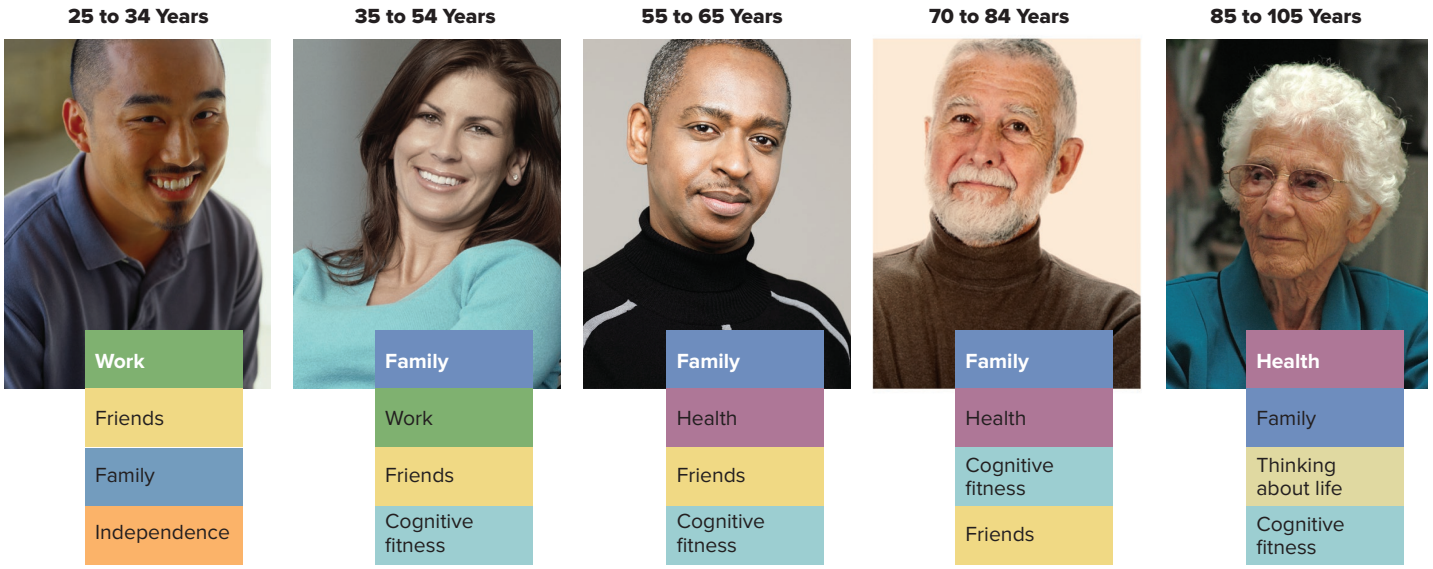

FIGURE 4

DEGREE OF PERSONAL LIFE INVESTMENT AT DIFFERENT POINTS IN LIFE. Shown here are the top four domains of personal life investment at different points in life. The highest degree of investment is listed at the top (for example, work was the highest personal investment from 25 to 34 years of age, family from 35 to 84, and health from 85 to 105).

the attainment of *meaningful* goals, that makes life satisfying. In one study, younger adults were more likely to assess their well-being in terms of accomplishments and careers, whereas older adults were more likely to link well-being with good health and the ability to accept change. In addition, emotion-related goals become increasingly important for older adults (Carstensen, 2019).

In one cross-sectional study, the personal life investments of 25- to 105-year-olds were assessed (Staudinger, 1996) (see Figure 4). From 25 to 34 years of age, participants said that they personally invested more time in work, friends, family, and independence, in that order. From 35 to 54 and 55 to 65 years of age, family became more important to them than friends in terms of their personal investment. Little change occurred in the rank ordering of persons 70 to 84 years old, but for participants 85 to 105 years old, health became the most important personal investment. Thinking about life showed up for the first time on the most important list for those who were 85 to 105 years old.

identity versus identity confusion Erikson's fifth stage of development, which occurs during the adolescent years; adolescents are faced with finding out who they are, what they are all about, and where they are going in life.

Who am I? What am I all about? What am I going to do with my life? What is different about me? How can I make it on my own? These questions reflect the search for an identity. By far the most comprehensive and provocative theory of identity development is Erik Erikson's. In this section, we examine his views on identity and some contemporary thoughts on identity. We also discuss research on how identity develops and how social contexts influence that development.

WHAT IS IDENTITY?

Identity is a self-portrait composed of many pieces, including the following:

- The career and work path the person wants to follow (vocational/career identity)
- Whether the person is conservative, liberal, or middle-of-the-road (political identity)
- The person's spiritual beliefs (religious identity)
- Whether the person is single, married, divorced, and so on (relationship identity)
- The extent to which the person is motivated to achieve and is intellectually active (achievement, intellectual identity)
- Whether the person is heterosexual, homosexual, bisexual, or transgendered
- Which part of the world or country a person is from and how intensely the person identifies with his or her cultural heritage (cultural/ethnic identity)
- The kinds of things a person likes to do, which can include sports, music, hobbies, and so on (interests)
- The individual's personality characteristics, such as being introverted or extraverted, anxious or calm, friendly or hostile, and so on (personality)
- The individual's body image (physical identity)

When identity development has been studied, researchers mostly have looked at it in a general way rather than examining how the timing and nature of identity development might vary for these different components of identity. Currently, too little research attention has been given to these and other domains of identity (Neblett, Roth, & Syed, 2019).

ERIKSON'S VIEW

Questions about identity surface as common, virtually universal, concerns during adolescence. Some decisions made during adolescence might seem trivial, such as whom to date, whether or not to break up, which major to study, whether to study or play, whether or not to be politically active, and so on. Over the years of adolescence, however, such decisions begin to form the core of what the individual is all about as a human being—what is called his or her identity.

It was Erik Erikson (1950, 1968) who first understood the importance of identity questions to understanding adolescent development. Identity is now believed to be a key aspect of adolescent development because of Erikson's masterful thinking and analysis. His ideas reveal rich insights into adolescents' thoughts and feelings, and reading one or more of his books is worthwhile. A good starting point is *Identity: Youth and Crisis* (1968).

According to Erikson's theory, adolescents go through a developmental stage that he called **identity versus identity confusion.** Erikson stated that during this stage—the fifth of his eight stages in the life span—adolescents are faced with deciding who they are, what they are all about, and where they are going in life. These questions about identity occur throughout life, but they become especially important for adolescents. Erikson maintained that adolescents face an overwhelming number of choices. As they gradually come to realize that they will be responsible for themselves and their own lives, adolescents search for what those lives are going to be.

The search for an identity during adolescence is aided by a **psychosocial moratorium,** which is Erikson's term for the gap between childhood security and adult autonomy. During this period, society leaves adolescents relatively free of responsibilities, which allows them to try out different identities. Adolescents in effect search their culture's identity files, experimenting with different roles and personalities. They may want to pursue one career one month (lawyer, for example) and another career the next month (doctor, actor, teacher, social worker, or astronaut, for example). They may dress neatly one day, sloppily the next. This experimentation is a deliberate effort on the part of adolescents to find out where they fit into the world. Most adolescents eventually discard undesirable roles.

Youth who successfully cope with conflicting identities emerge with a new sense of self that is both refreshing and acceptable. Adolescents who do not successfully resolve this identity crisis suffer what Erikson called identity confusion. The confusion takes one of two courses: Individuals withdraw, isolating themselves from peers and family, or they immerse themselves in the world of peers and lose their identity in the crowd.

Erik Erikson.
Bettmann/Getty Images

SOME CONTEMPORARY THOUGHTS ON IDENTITY

Contemporary views of identity development suggest that it is a lengthy process, in many instances more gradual and less cataclysmic than Erikson's use of the term *crisis* implies (McLean & others, 2021). Resolution of the identity issue during adolescence and emerging adulthood does not mean that identity will be stable through the remainder of one's life. An individual who develops a healthy identity is flexible and adaptive, open to changes in society, in relationships, and in careers. This openness ensures numerous reorganizations of identity throughout the individual's life.

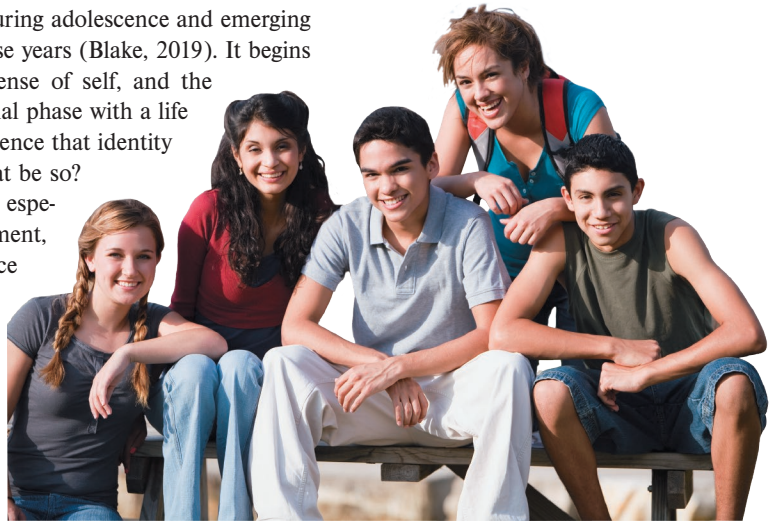
Identity formation neither happens neatly nor is it usually cataclysmic (Moffitt, Juang, & Syed, 2020). At the bare minimum, it involves commitment to a vocational direction, an ideological stance, and a sexual orientation. Synthesizing the components of identity can be a long, drawn-out process, with many negations and affirmations of various roles. Identity development happens in bits and pieces. Decisions are not made once and for all but must be made again and again (Ferrer-Wreder & Kroger, 2020).

One way that researchers are examining identity changes in depth is to use a narrative approach. This involves asking individuals to tell their life stories and evaluate the extent to which their stories are meaningful and integrated (McAdams, 2021; McLean & others, 2021). The term *narrative identity* "refers to the stories people construct and tell about themselves to define who they are for themselves and others. Beginning in adolescence and young adulthood, our narrative identities are the stories we live by" (McAdams, 2021).

psychosocial moratorium Erikson's term for the gap between childhood security and adult autonomy that adolescents experience as part of their identity exploration.

DEVELOPMENTAL CHANGES

Although questions about identity may be especially important during adolescence and emerging adulthood, identity formation neither begins nor ends during these years (Blake, 2019). It begins with the appearance of attachment, the development of the sense of self, and the emergence of independence in infancy; the process reaches its final phase with a life review and integration in old age. But for Erikson, it is in adolescence that identity begins to be a key dimension of individuals' lives. Why might that be so? What is important about identity development in adolescence, especially late adolescence, is that for the first time, physical development, cognitive development, and socioemotional development advance to the point at which the individual can sort through and synthesize childhood identities and identifications to construct a viable path toward adult maturity.



What are some contemporary thoughts about identity formation and development?
Somos/Veer/Caroline Mowry/Getty Images

Identity Statuses How do individual adolescents go about the process of forming an identity? Eriksonian researcher James Marcia (1980, 1994) analyzed Erikson's theory of identity development and concluded that it involves four statuses of identity, or ways of resolving the identity crisis: identity diffusion, identity foreclosure, identity moratorium, and identity achievement. What determines an individual's identity status?

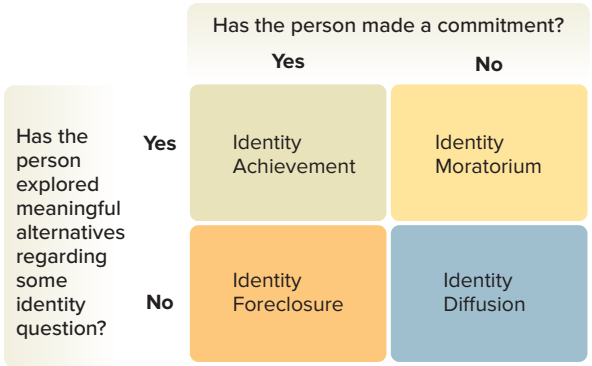


FIGURE **5**

MARCIA'S FOUR STATUSES OF IDENTITY.

Marcia classifies individuals based on the existence or extent of their crisis or commitment (see Figure 5). **Crisis** is defined as a period of identity development during which the individual explores alternatives. Most researchers use the term *exploration* rather than *crisis*. **Commitment** is a personal investment in identity.

The four statuses of identity are as follows:

- **Identity diffusion** is the status of individuals who have not yet experienced a crisis or made any commitments. Not only are they undecided about occupational and ideological choices, but they are also likely to show little interest in such matters.
- **Identity foreclosure** is the status of individuals who have made a commitment but have not experienced a crisis. This occurs most often when parents hand down commitments to their adolescents, usually in an authoritarian way, before adolescents have had a chance to explore different approaches, ideologies, and vocations on their own.
- **Identity moratorium** is the status of individuals who are in the midst of a crisis but whose commitments are either absent or only vaguely defined.
- **Identity achievement** is the status of individuals who have undergone a crisis and have made a commitment.

Let's explore some examples of Marcia's identity statuses. Thirteen-year-old Sarah has neither begun to explore her identity in any meaningful way nor made an identity commitment; she is *identity diffused*. Eighteen-year-old Tim's parents want him to be a medical doctor, so he is planning on majoring in premedicine in college and has not explored other options; he is *identity foreclosed*. Nineteen-year-old Sasha is not quite sure what life paths she wants to follow, but she recently went to the counseling center at her college to find out about different careers; she is in *identity moratorium* status. Twenty-one-year-old Marcelo extensively explored several career options in college, eventually getting his degree in science education, and is looking forward to his first year of teaching high school students; he is *identity achieved*. These examples focused on the career dimension of identity, but keep in mind that identity has a number of dimensions.

During early adolescence, most youth are primarily in the identity statuses of *diffusion, foreclosure*, or *moratorium*. According to Marcia (1987, 1996), at least three aspects of the young adolescent's development are important to identity formation. Young adolescents must be confident that they have parental support, must have an established sense of industry, and must be able to take a self-reflective stance toward the future.

Belgian psychologists Koen Luyckx and his colleagues (Hatano, Sugimura, & Luyckx, 2020; Luyckx & others, 2018; Mattys & others, 2020) have proposed an extension of Marcia's concepts of exploration and commitment. The revisionist theorizing stresses that effective identity development involves evaluating identity commitments on a continuing basis.

Some critics of the identity status approach argue that it does not lead to a deep enough understanding of identity development. The newer *dual cycle identity model* separates out identity development into two separate processes: (1) a formation cycle that relies on exploration in breadth and identification with commitment; and (2) a maintenance cycle that involves exploration in depth as well as reconsideration of commitments (Luyckz & others, 2018; van Doeselaar & others, 2020). A longitudinal study from early adolescence into emerging adulthood confirmed the existence of a dual cycle identity formation process (Becht & others, 2021).

For example, consider a first-year college student who makes a commitment to become a lawyer. Exploring this commitment in depth might include finding out as much as possible about what is involved in being a lawyer, such as educational requirements, the work conducted by lawyers in different areas, what types of college classes might be beneficial for this career, and so on. It might also include talking with several lawyers about their profession. As a result of this in-depth exploration, the college student may become more confident that being a lawyer is the career that best suits her. As she goes through the remainder of her college years, she will continue to evaluate the commitment she has made to becoming a lawyer and may change her commitment as she continues to gather new information and reflect on the life path she wants to take.

Researchers have developed a consensus that the key changes in identity are most likely to take place in emerging adulthood, the period from about 18 to 25 years of age, not during adolescence (Mattys & others, 2020). One study found that as individuals matured from early adolescence to emerging adulthood, they increasingly engaged in in-depth exploration of their

crisis A period of identity development during which the individual is exploring alternatives.

commitment A personal investment in identity.

identity diffusion Marcia's term for the status of individuals who have not yet experienced a crisis (explored meaningful alternatives) or made any commitments.

identity foreclosure Marcia's term for the status of individuals who have made a commitment but have not experienced a crisis.

identity moratorium Marcia's term for the status of individuals who are in the midst of a crisis but whose commitments are either absent or vaguely defined.

identity achievement Marcia's term for the status of individuals who have undergone a crisis and have made a commitment.

identity (Klimstra & others, 2010). Alan Waterman (1985, 1992) has found that from the years preceding high school through the last few years of college, the number of individuals who are identity achieved increases, whereas the number of individuals who are identity diffused decreases.

Many young adolescents are identity diffused. College upperclassmen are more likely than high school students or college freshmen to be identity achieved. Why might college produce key changes in identity? Increased complexity in the reasoning skills of college students combined with a wide range of new experiences that highlight contrasts between home and college and between themselves and others stimulate them to reach a higher level of integrating various dimensions of their identity (Phinney, 2008). College contexts serve as a virtual "laboratory" for identity development through such experiences as diverse coursework and exposure to peers from diverse backgrounds. Also, one of emerging adulthood's key themes is not having many social commitments, which gives individuals considerable independence in developing a life path (Arnett, 2016; Arnett & Mitra, 2020).

How does identity change in emerging adulthood?
Monkey Business Images/Shutterstock

A meta-analysis of 124 studies revealed that during adolescence and emerging adulthood, identity moratorium status rose steadily to age 19 and then declined; identity achievement rose across late adolescence and emerging adulthood; and foreclosure and diffusion statuses declined across the high school years but fluctuated in the late teens and emerging adulthood (Kroger, Martinussen, & Marcia, 2010). The studies also found that a large proportion of individuals were not identity achieved by the time they reached their twenties. Also, in a recent study of Flemish 17- to 26-year-olds in northern Belgium, commitment and responsibility characterized older participants and employed participants more than younger participants and unemployed participants (Mattys & others, 2020). And in another recent study, emerging adults who were identity diffused were more likely to present an ideal self and a false self on Facebook, indicating they were less realistic and more socially desirable in their online self-presentation (Michikyan, 2020).

Nonetheless, many young adults have a stable identity. A recent study examined identity development from 25 to 33 years of age (Eriksson & others, 2020). In this study, fewer individuals were characterized by a moratorium status and more by an identity achievement status as they became older during this time frame. Also, stable identity statuses with established commitments (identity achievement and foreclosure) were by far the most common patterns across this time period.

Resolution of the identity issue during adolescence and emerging adulthood does not mean that identity will be stable through the remainder of life (Ferrer-Wreder & Kroger, 2020). Many individuals who develop positive identities follow what are called "MAMA" cycles; that is, their identity status changes from *m*oratorium to *a*chievement to *m*oratorium to *a*chievement (Marcia, 1994). These cycles may be repeated throughout life (Francis, Fraser, & Marcia, 1989). Marcia (2002) points out that the first identity should not be viewed as the final product.

Researchers have shown that identity consolidation—the process of refining and enhancing the identity choices that are made in emerging adulthood—continues well into early adulthood and possibly into the early part of middle adulthood (Ferrer-Wreder & Kroger, 2020). Further, as individuals move from early to middle adulthood, they become more certain about their identity. For example, a longitudinal study of college women found that identity certainty increased from the thirties through the fifties (Stewart, Ostrove, & Helson, 2001).

IDENTITY AND SOCIAL CONTEXTS

Social contexts influence an adolescent's identity development (Moffitt, Juang, & Syed, 2020). Questions we will explore in this regard are: Do family relationships influence identity development? What roles do peers, romantic relationships, and the digital world play in identity formation? How are culture, ethnicity, and race linked to identity development?

developmental **connection**

Attachment

Even while adolescents seek autonomy, attachment to parents is important; secure attachment in adolescence is linked to a number of positive outcomes. Connect to "Emotional Development and Attachment."

individuality Characteristic consisting of two dimensions: self-assertion, the ability to have and communicate a point of view; and separateness, the use of communication patterns to express how one is different from others.

connectedness Characteristic consisting of two dimensions: mutuality, which is sensitivity to and respect for others' views; and permeability, which is openness to others' views.

Family Processes Parents are important figures in the adolescent's development of identity (Umana-Taylor & others, 2020). One study found that poor communication between mothers and adolescents, as well as persistent conflicts with friends, was linked to less positive identity development (Reis & Youniss, 2004). Catherine Cooper and her colleagues (Cooper, 2011; Cooper, Behrens, & Trinh, 2009; Cooper & Grotevant, 1989) have found that a family atmosphere that promotes both individuality and connectedness is important to the adolescent's identity development:

- **Individuality** consists of two dimensions: self-assertion, which is the ability to have and communicate a point of view; and separateness, which is the use of communication patterns to express how one is different from others.
- **Connectedness** also consists of two dimensions: mutuality, which involves sensitivity to and respect for others' views; and permeability, which involves openness to others' views.

Identity and Peer/Romantic Relationships Researchers have recently found that the capacity to explore one's identity during adolescence and emerging adulthood is linked to the quality of friendships and romantic relationships (Umana-Taylor & others, 2020). In one study, friends were often a safe context for exploring identity-related experiences, providing a means of testing how self-disclosing comments are viewed by others (McLean & Jennings, 2012).

In terms of links between identity and romantic relationships in adolescence and emerging adulthood, two individuals in a romantic relationship are both in the process of constructing their own identities and each person provides the other with a context for identity exploration (Pittman & others, 2011). The extent of their secure attachment with each other can influence how each partner constructs his or her own identity.

Identity Development and the Digital Environment For today's adolescents and emerging adults, the contexts involving the digital world, especially social media platforms such as Instagram, Snapchat, and Facebook, have introduced new ways for youth to express and explore their identity (Davis, 2020, 2021; Davis & others, 2020). Adolescents and emerging adults often cast themselves as positively as they can on their digital devices—posting their most attractive photos and describing themselves in idealistic ways, repeatedly editing and reworking their online self-portraits to enhance them. Adolescents' and emerging adults' online world provides extensive opportunities for both expressing their identity and getting feedback about it (Davis, 2021). Of course, such feedback is not always positive, just as in their offline world. We will have much more to say about the roles of social media in adolescence and emerging adulthood in "Peers and the Sociocultural World."

One adolescent girl, 16-year-old Michelle Chin, made these comments about ethnic identity development: "My parents do not understand that teenagers need to find out who they are, which means a lot of experimenting, a lot of mood swings, a lot of emotions and awkwardness. Like any teenager, I am facing an identity crisis. I am still trying to figure out whether I am a Chinese American or an American with Asian eyes." *What are some other aspects of developing an ethnic identity in adolescence?*
Red Chopsticks/Getty Images

Cultural, Ethnic, and Racial Identity Most research on identity development has historically been based on data obtained from adolescents and emerging adults in the United States, especially those who are non-Latinx Whites (Schwartz & others, 2020). Many of these individuals have grown up in cultural contexts that value individual autonomy. However, in many countries around the world, adolescents and emerging adults have grown up influenced by a collectivist emphasis on fitting in with the group and connecting with others (Kulich & others, 2021). The collectivist emphasis is especially prevalent in East Asian countries such as China. Researchers have found that self-oriented identity exploration may not be the main process through which identity achievement is attained in East Asian countries (Schwartz & others, 2012). Rather, East Asian adolescents and emerging adults may develop their identity through identification with and imitation of others in their cultural group (Bosma & Kunnen, 2001). The emphasis on interdependence in East Asian cultures includes an emphasis on adolescents and emerging adults accepting and embracing social and family roles (Berman & others, 2011). Thus, some patterns of identity development, such as the foreclosed status, may be more adaptive in East Asian countries than in North American countries (Cheng & Berman, 2012).

Seth Schwartz and his colleagues (2012, 2020) pointed out that while everyone identifies with a particular "culture," many individuals in cultural majority groups

take their cultural identity for granted. Thus, many adolescents and emerging adults in the cultural majority of non-Latinx Whites in the United States likely don't spend much time thinking of themselves as "White American." However, for many adolescents and emerging adults who have grown up as a member of an ethnic minority group in the United States or emigrated from another country, cultural dimensions likely are an important aspect of their identity. Researchers have found that at both the high school and college levels, Latinx students were more likely than non-Latinx White students to indicate that their cultural identity was an important dimension of their overall self-concept (Urdan, 2012).

Throughout the world, ethnic minority groups have struggled to maintain their ethnic identities while blending in with the dominant culture (Wang & Yip, 2020). **Ethnic identity** is an enduring aspect of the self that includes the subjective sense of membership in an ethnic group (Mexican American, for example), along with the attitudes and feelings related to self-labeling in that membership (Banales & others, 2020). Thus, for adolescents from ethnic minority groups, the process of identity formation has an added dimension: the choice between two or more sources of identification—their own ethnic group and the mainstream, or dominant, culture (Cheon & others, 2020). Many adolescents resolve this choice by developing a **bicultural identity.** That is, they identify in some ways with their ethnic group and in other ways with the majority culture (Sharma, Shaligram, & Yoon, 2020). A study of Mexican American and Asian American college students found that they identified both with the American mainstream culture and with their culture of origin (Devos, 2006).

Time is another aspect that influences ethnic identity. The indicators of identity often differ for each succeeding generation of immigrants (Phinney, 2006; Phinney & Vedder, 2013). First-generation immigrants are likely to be secure in their identities and unlikely to change much; they may or may not develop a new identity. The degree to which they begin to feel "American" appears to be related to whether or not they learn English, develop social networks beyond their ethnic group, and become culturally competent in their new country. Second-generation immigrants are more likely to think of themselves as "American"—possibly because citizenship is granted at birth. For second-generation immigrants, ethnic identity is likely to be linked to retention of their ethnic language and social networks. In the third and later generations, the issues become more complex. Broad social factors may affect the extent to which members of this generation retain their ethnic identities. For example, media images may influence whether members of an ethnic group will continue to identify with their group and retain parts of its culture. Discrimination may force people to see themselves as cut off from the majority group and encourage them to seek the support of their own ethnic culture.

Adriana Umana-Taylor and her colleagues (2020) are also increasingly finding that a positive ethnic identity is related to positive outcomes for ethnic minority adolescents. For example, one study found that Asian American adolescents' ethnic identity was associated with high self-esteem, positive relationships, academic motivation, and lower levels of depression over time (Kiang, Witkow, & Champagne, 2013). In another study researchers found that ethnic identity was a strong predictor of positive mental health among African American college students (McClain & others, 2016). Further, in a recent study, Latinx youth showed enhanced resilience against discrimination encounters when they had more family ethnic socialization experiences and engaged in greater ethnic identity exploration and resolution (Martinez-Fuentes, Jager, & Umana-Taylor, 2021). In addition, in a recent study, strong ethnic group affiliation and connection served a protective function in reducing risk for psychiatric problems (Anglin & others, 2018). To read about one individual who guides Latinx adolescents in developing a positive identity, see the *Connecting with Careers* profile.

Given the history of race and discrimination in the United States, the identities of adolescents and emerging adults are also influenced by their social status in a racial hierarchy that privileges individuals who are non-Latinx White (Hope, Cryer-Coupet, & Stokes, 2020). While race is understood to be a social concept, the lived experience of being a racial minority and treated differently can greatly impact identity formation. **Racial identity** is the collective identity of any group of people socialized to think of themselves as a racial group (Helms & Cook, 1999). Researchers have found that racial identity is positively associated with self-esteem (Rowley & others, 1998) and academic attitudes (Chavous & others, 2003) among African American students. In a recent study of African American 13- to 17-year-old girls, general and gendered racial socialization about pride were linked to positive feelings about being African American, while oppressive messages about African American women were associated with

ethnic identity The subjective sense of ethnic group membership that involves self-labeling (Mexican American, for example) and evaluation of one's ethnic group.

bicultural identity Identifying both with one's own ethnic minority group and with the majority culture.

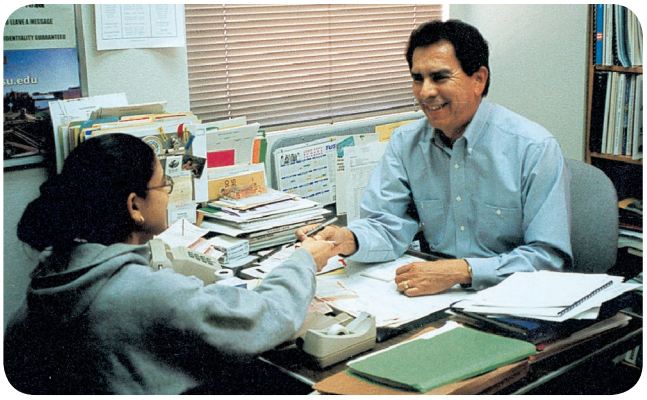
racial identity The collective identity of any group of people socialized to think of themselves as a racial group.

connecting with careers

Armando Ronquillo, High School Counselor

Armando Ronquillo is a high school counselor and admissions advisor at Pueblo High School in a low-income area of Tucson, Arizona. More than 85 percent of the students have a Latinx background. Ronquillo was named the top high school counselor in the state of Arizona in 2000. Ronquillo especially works with Latinx students to guide them in developing a positive identity. He talks with them about their Latinx background and what it's like to have a bicultural identity—preserving important aspects of their Latinx heritage while also doing what is necessary to be successful in the contemporary culture of the United States.

Ronquillo believes that helping students stay in school and getting them to think about the lifelong opportunities provided by a college education will benefit their identity development. He also works with parents to help them understand that sending their child to college can be doable and affordable.



Armando Ronquillo counsels a Latina high school student about college.

For more information about what school counselors do, see the Careers in Life-Span Development appendix.

depressive symptoms (Stokes & others, 2020). Also, another recent study of 11- to 12-year-olds found that more frequent discrimination by peers was linked to lower ethnic-racial commitment (Del Toro, Hughes, & Way, 2021). Further, a recent study of adolescents revealed that on days when adolescents reported more negative peer ethnic/racial interaction (ethnic/racial discrimination and teasing, for example), they had lower school engagement (Wang, 2021). On days when they reported more positive peer ethnic/racial interaction (support against discrimination, for example), they engaged in more prosocial behavior. In addition, a research review of Latinxs concluded that perceived discrimination was linked to poorer mental health but that having a greater sense of ethnic pride attenuated this link (Andrade, Ford, & Alvarez, 2021).

There is also emerging research which suggests that ethnic identity and racial identity are best conceptualized as a singular concept of ethnic-racial identity (ERI), where the focus is on ERI development (Atkin & Yoo, 2021; Schwartz & others, 2014). In a recent study of Cherokee young adolescents' ERI, both girls and boys reported strong positive attitudes about being a Cherokee (Hoffman, Kurtz-Coates, & Shaheed, 2021). However, the adolescents' perceptions that others hold Cherokees in high regard decreased across grade levels. Overall, high levels of ERI have been found to be a source of protection from discrimination while also being associated with increased vulnerability (Yip, 2018).

3 Personality

LG3 Describe personality and its development in adulthood.

Trait Theories and the Big Five Factors of Personality | Views on Adult Personality Development | Generativity | Stability and Change

Earlier in the chapter, personality was defined as the enduring personal characteristics of individuals. Personality psychologists use many strategies to better understand the enduring characteristics of individuals (Cloninger, 2021). Some of them study the overall personality of individuals; some come up with a list of traits that best describe individuals; and others zero in on specific traits or characteristics, such as being introverted or extraverted (Weiss & Deary, 2021).

In other chapters we have considered several major personality theories—psychoanalytic theories and the social cognitive theory of Albert Bandura. You might wish to review those theories at this time. Here our exploration of personality focuses on trait theory, several views of personality development in adulthood, and studies of stability and change in personality during adulthood.

TRAIT THEORIES AND THE BIG FIVE FACTORS OF PERSONALITY

Trait theories state that personality consists of broad dispositions, called traits, that tend to produce characteristic responses (De Raad & Barelds, 2021). In other words, people can be described in terms of the basic ways they behave, such as whether they dominant and assertive or compliant and accepting (Hakulinen & others, 2021). Although trait theorists disagree about which traits make up personality, they agree that traits are the foundation of personality.

In "Emotional Development and Attachment," we described the development of temperament in infants and children (Rothbart, Posner, & Sheese, 2021). For example, we discussed Kagan's concept of inhibition to the unfamiliar, as well as Rothbart and Bates' categories of extraversion/surgency, negative affectivity, and effortful control. Many developmental psychologists use the term "temperament" when talking about personality-like categories in infancy and childhood (Kagan, 2019). You might want to review the discussion of temperament in "Emotional Development and Attachment" to get a sense of the early development of personality-like categories.

trait theories Theories emphasizing that personality consists of broad dispositions, called traits, which tend to produce characteristic responses.

Big Five Factors of Personality

One trait theory that has received considerable attention involves the **Big Five factors of personality**—the view that personality is made up of openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism (see Figure 6). (Notice that if you create an acronym from these trait names, you will get the word *OCEAN*.) A number of research studies point toward these five factors as important dimensions

Big Five factors of personality The view that personality is made up of five factors: openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism.

FIGURE 6

THE BIG FIVE FACTORS OF PERSONALITY. Each of the broad super traits encompasses more narrow traits and characteristics. Use the acronym OCEAN to remember the Big Five personality factors (openness, conscientiousness, extraversion, agreeableness, neuroticism).

An adolescent with a high level of conscientiousness organizes his daily schedule and plans how to use his time effectively. *What are some characteristics of conscientiousness?*
Mint Images/Getty Images

of personality (Atherton, Donnellan, & Robins, 2021; Costa & McCrae, 1998; Hakulinen & others, 2021; McCrae, 2021).

Evidence for the importance of the Big Five factors indicates that they are related to such important aspects of a person's life as physical health (Heilmayr & Friedman, 2021), mental health (Widiger & McCabe, 2021), intelligence (Schermer & Saklofske, 2021), cognitive functioning (Matthews, 2021), achievement (Szalma, 2021), work (Salgado, Anderson, & Moscoso, 2021), and relationships (Austin & others, 2021). The following research supports these links:

- *Openness to experience.* Individuals high in openness to experience are more likely to be tolerant of others (McCrae & Sutin, 2009); to have superior cognitive functioning, achievement, and IQ across the life span (Briley, Domiteaux, & Tucker-Drob, 2014); to experience success as entrepreneurs (Zhao, Seibert, & Lumpkin, 2010); and to have better health and well-being (Strickhouser, Zell, & Krizan, 2017). Openness to experience also is associated with successful aging, and it tends to decline in advance of death in older adults (Sharp & others, 2019).
- *Conscientiousness.* Individuals high in conscientiousness often do well in a variety of life domains (Roberts & Nickel, 2020). For example, they are likely to live longer (Chapman & others, 2020); to experience optimal aging, including positive affect, life satisfaction, and positive psychological well-being (Melendez & others, 2019); to have better health and less stress (Gartland & others, 2014; Strickhouser, Zell, & Krizan, 2017); to have higher levels of marital satisfaction (Sayehmiri & others, 2020) and overall life satisfaction (Heilmann & others, 2020); and to earn higher grade point averages in college (McAbee & Oswald, 2013). Highly conscientious individuals are less likely to engage in excessive screen time, including time spent on social networking sites (Yanez & others, 2020).
- *Extraversion.* Individuals high in extraversion are more likely than others to be satisfied in relationships (Toy, Nai, & Lee, 2016); to show less negative affect to stressors (Leger & others, 2016); and to have a higher level of perceived well-being (Ortet & others, 2020).
- *Agreeableness*. People who are high in agreeableness are likely to live longer (Graham & others, 2017); to be generous and altruistic (Caprara & others, 2010); to have more satisfying romantic relationships (Donnellan, Larsen-Rife, & Conger, 2005); and they are less likely to engage in physical activity (Hearon & Harrison, 2021) or to lie about themselves in online dating profiles (Hall & others, 2010).
- *Neuroticism*. People high in neuroticism are likely to die at a younger age than people with lower levels of neuroticism (Graham & others, 2017); to have worse health and report having more health complaints (Strickhouser, Zell, & Krizan, 2017); to be more drug dependent (Raketic & others, 2017); to have higher rates of anxiety, depressive, and obsessive-compulsive symptoms (Tonarely & others, 2020); and to have a lower level of marital satisfaction (Sayehmiri & others, 2020). Also, a recent study found that individuals characterized by high neuroticism avoided engaging in selfie-posting and selfie-editing while those with high extraversion and agreeableness engaged in more selfie-posting and selfie-editing (Chaudhari & others, 2019). And another recent study revealed that older adults with higher neuroticism and lower conscientiousness had more difficulty in their cognitive control related to engaging in goal-directed behavior (Bell, Hill, & Stavrinos, 2020).

Optimism

Another important personality characteristic is **optimism,** which involves having a positive outlook on the future and minimizing problems (Baranski & others, 2021). Optimism is often referred to as a style of thinking.

Little research has been conducted on children's optimism, but one study did find that from 5 to 10 years of age children increasingly understood that thinking positively improves their emotional state and that thinking negatively makes it worse (Bamford & Lagattuta, 2012). In *The Optimistic Child*, Martin Seligman (2007) described how parents, teachers, and coaches can instill optimism in children, which he argues helps to make them more resilient and less likely to develop depression.

optimism A style of thinking that involves having a positive outlook on the future and minimizing problems.

In examining optimism in adolescents, one study found that having an optimistic style of thinking predicted a reduction in suicidal ideation for individuals who had experienced negative and potentially traumatic life events (Hirsch & others, 2009). Another study revealed that adolescents with an optimistic thinking style had a lower risk of developing depressive symptoms than their pessimistic counterparts (Patton & others, 2011). Other recent research with adolescents indicated that greater optimism was linked to decreased suicide risk and increased suicide protection (Yi & others, 2021). And a recent study of Latinx young adolescents revealed that higher resilience and school attachment predicted a higher level of optimism (Taylor & others, 2020).

Researchers increasingly are finding that optimism is linked to better adjustment, better health, and increased longevity (Ait-Hadad & others, 2020; Felt & others, 2020). A recent study revealed that college students who were pessimistic had more anxious mood and stress symptoms than those who were optimistic (Lau & others, 2017). A study involving adults 50 years of age and older revealed that being optimistic and having an optimistic spouse were associated with better health and physical functioning (Kim, Chopik, & Smith, 2014). Further, another study of married couples found that the worst health outcomes occurred when both spouses decreased in optimism across a four-year time frame (Chopik, Kim, & Smith, 2018). Also, in a recent study, lonely individuals who were optimistic had a lower suicide risk than their counterparts who were more pessimistic (Chang & others, 2018). In addition, a recent study revealed that regardless of growing up in disadvantaged circumstances as a child, being optimistic as an adult was linked to being a non-smoker, having a healthy diet, and having a healthy body mass index (Non & others, 2020). And a recent study found that greater optimism at 85 and 90 years of age was associated with increased survival rates from 85 to 90 and from 90 to 95 years of age (Jacobs, Maaravi, & Stessman, 2021).

Trait-Situation Interaction The trait theories have identified a number of characteristics that are important to consider when attempting to understand an individual's personality (Weiss & Deary, 2021). The trait approach also has led to advances in the assessment of personality through the development of numerous personality tests (Boyle & Helmes, 2021). However, some psychologists note that the trait approach gives too little attention to environmental factors and puts too much emphasis on stability (Reis & Holmes, 2019). These criticisms initially were leveled by social cognitive theorist Walter Mischel (1968). Mischel argued that personality often changes according to the situation. Thus, individuals may behave very differently at a party from the way they would behave in a library.

Today, most personality psychologists believe that personality is a product of *trait-situation interaction*. In other words, both traits and situational (context) factors must be considered to understand personality (Asendorpf & Rauthmann, 2021). Also, some people are more consistent on some traits while other people are consistent on other traits.

Might some of the Big Five factors be related to how accepting individuals are of cultural diversity? To find out, read the *Connecting with Research* interlude.

VIEWS ON ADULT PERSONALITY DEVELOPMENT

Two important perspectives on adult development are the stage-crisis view and the life-events approach. In examining these approaches, we discuss the extent to which adults experience a midlife crisis and consider how life events influence the individual's development.

The Stage-Crisis View Erikson's theory, which we discussed earlier, is a stage-crisis view. Here we describe the view of Daniel Levinson and examine the concept of a midlife crisis.

Levinson's Seasons of a Man's Life In *The Seasons of a Man's Life*, clinical psychologist Daniel Levinson (1978) reported the results of extensive interviews with 40 middle-aged men. The interviews were conducted with hourly workers, business executives, academic

Is an Individual's Personality Profile Linked to Their Diversity Orientation and Attitudes about Diversity?

Courtesy Suejung Han

Suejung Han
Key Points:
- personality
- attitudes towards diversity
- openness

Researcher Suejung Han (2021), a professor of Korean descent, has conducted many studies on personality and related clinical disorders. In one research investigation that included two studies, she explored the association between personality profiles, using the Big Five personality factors, and openness to diversity among college students (Han and Pistole, 2017). Universal-Diverse Orientation (UDO) was used as a measure of openness to diversity. UDO includes an appreciation for the things all humans have in common, such as a parent's love for a child, and the things that make each of us unique, such as cultural factors.

In the first study, 338 undergraduate students completed a 44-item measure of the Big Five personality factors that asked if they viewed themselves as having certain tendencies, such as coming up with new ideas or doing a thorough job on tasks. They also completed a 15-item measure of UDO that asked how strongly they agreed or disagreed with statements such as "People with disabilities can teach me things I could not learn elsewhere." Research analysis indicated the most important finding was that Openness to Experience and Agreeableness were the strongest predictors of high UDO.

In the second study, a new group of participants were recruited in order to cross-validate the findings of the first study and to look deeper into the link between UDO and particular facets of each of the Big Five personality factors. A facet is similar to a characteristic. For example, Openness to Experience includes the facets of creative imagination and a preference for variety over routine.

In this second study, undergraduate students completed a more in-depth questionnaire measuring the Big Five personality factors with 240 items, along with the same measure of UDO used in the first study. Statistical analysis indicated that Openness to Experience was a strong predictor of UDO. Unlike the first study, however, data from this group of undergraduates using the more in-depth questionnaire revealed that Agreeableness was not influential, while low Neuroticism and high Conscientiousness were associated with UDO. The differences in findings highlights the need to replicate research to better understand complex concepts.

This research indicated that certain personality traits are linked to having an open attitude toward diversity (UDO). Those who are open to diversity not only have personality traits that help them appreciate cultural diversity and diverse perspectives but also have an ethical motivation to better understand various aspects of diversity. Individuals who are open to diversity have a positive attitude, genuine trust, and appreciation of diverse individuals.

How might these findings be used to create classroom activities designed to increase appreciation for individual and cultural diversity?

biologists, and novelists. Levinson bolstered his conclusions with information from the biographies of famous men and the development of memorable characters in literature. Although Levinson's major focus was midlife change, he described a number of stages and transitions in the life span, as shown in Figure 7.

Levinson emphasizes that developmental tasks must be mastered at each of these stages. In early adulthood, the two major tasks are exploring the possibilities for adult living and developing a stable life structure. Levinson sees the twenties as a *novice phase* of adult development. At the end of one's teens, a transition from dependence to independence should occur. This transition is marked by the formation of a dream—an image of the kind of life the youth wants to have, especially in terms of a career and marriage. The novice phase is a time of reasonably free experimentation and of testing the dream in the real world.

From about age 28 to 33, a young man goes through a transition period in which he must face the more serious question of determining his goals. During his thirties, he usually focuses on family and career development. In the later years of this period, he enters a phase of Becoming One's Own Man (or BOOM, as Levinson calls it). By age 40, he has reached a stable location in his career, has outgrown his earlier, more tenuous attempts at learning to become an adult, and now must look forward to the kind of life he will lead as a middle-aged adult.

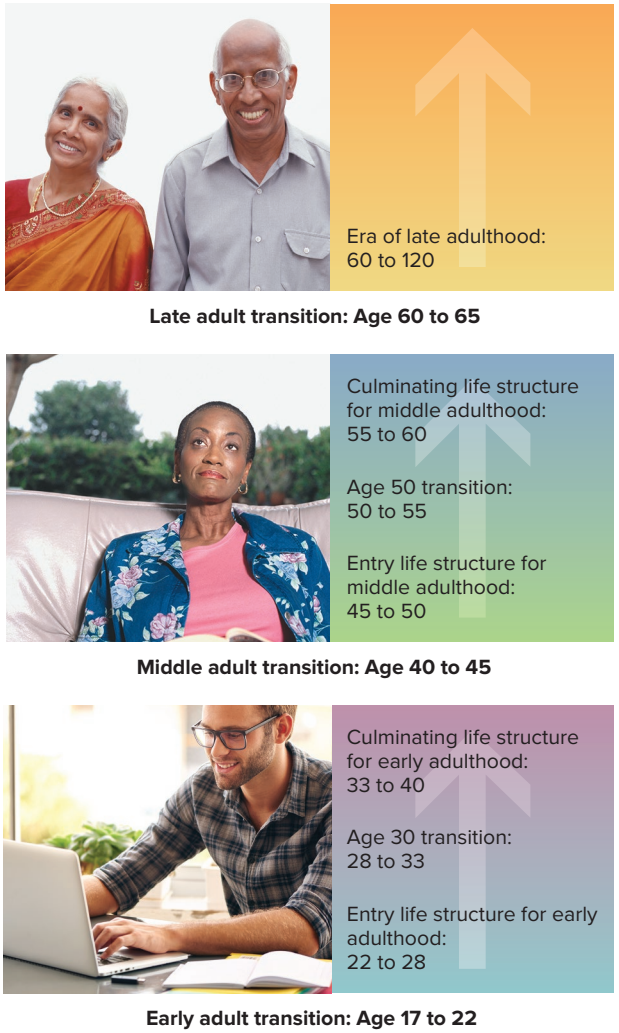
According to Levinson, the transition to middle adulthood lasts about five years (ages 40 to 45) and requires the adult male to come to grips with four major conflicts that have existed in his life since adolescence: (1) being young versus being old, (2) being destructive versus being constructive, (3) being masculine versus being feminine, and (4) being attached to others versus being separated from them. Among the men Levinson interviewed, 70 to 80 percent found the midlife transition tumultuous and psychologically painful, as many aspects of their lives came into question. According to Levinson, the success of the midlife transition depends on how effectively the individual reduces the polarities and accepts each of them as an integral part of his being.

The original Levinson data included no females. However, Levinson (1987, 1996) subsequently reported that his stages, transitions, and the crisis of middle age hold for females as well as males.

Midlife Crises Levinson (1978) views midlife as a crisis, believing that the middle-aged adult is suspended between the past and the future, trying to cope with this gap that threatens life's continuity. George Vaillant (1977) concludes that just as adolescence is a time for detecting parental flaws and discovering the truth about childhood, the forties are a decade of reassessing and recording the truth about the adolescent and adulthood years. However, whereas Levinson sees midlife as a crisis, Vaillant notes that only a minority of adults experience a midlife crisis:

> Just as pop psychologists have reveled in the not-so-common high drama of adolescent turmoil, also the popular press, sensing good copy, have made all too much of the mid-life crisis. The term *mid-life crisis* brings to mind some variation of the renegade minister who leaves behind four children and the congregation that loved him in order to drive off in a magenta Porsche with a 25-year-old striptease artiste. As with adolescent turmoil, mid-life crises are much rarer in community samples. (Vaillant, 1977, pp. 222–223)

Vaillant's study—called the Grant Study—involved a follow-up of Harvard University men in their early thirties and in their late forties who initially had been interviewed as undergraduates. Other research has also found that midlife is not characterized by pervasive crises. For example, a longitudinal study of 2,247 individuals found few midlife crises (McCrae & Costa, 1990). The emotional well-being of these individuals did not significantly decrease during middle age (see Figure 8). In fact, some studies have documented psychological gains among middle-aged adults. For example, one study revealed that individuals from 40 to 60 years of age were less nervous and worried than those under 40. The middle-aged adults reported a growing sense of control in their work as well as increased financial security, greater environmental mastery (ability to handle daily responsibilities), and more autonomy than their younger counterparts.



Era of late adulthood:

Age 30 transition:
28 to 33
Entry life structure for early adulthood:
22 to 28
Early adult transition: Age 17 to 22

FIGURE 7

LEVINSON'S PERIODS OF ADULT DEVELOPMENT. According to Levinson, adulthood has three main stages, which are surrounded by transition periods. Specific tasks and challenges are associated with each stage.

(*top to bottom*): Amos Morgan/Photodisc/Getty Images; Corbis/VCG/Getty Images; Nako Photography/Shutterstock

Adult development experts have become virtually unanimous in their belief that midlife crises have been exaggerated (Lachman & Kranz, 2010; Pudrovska, 2009). In sum, there is a consensus that (1) the stage theories place too much emphasis on crises in development, especially midlife crises; and (2) there often is considerable individual variation in the way people experience the stages, a topic that we explore next.

> Mid-life crises are greatly exaggerated in America.
>
> —GEORGE VAILLANT
> *Contemporary Psychologist, Harvard University*

Individual Variations Stage theories especially focus on the universals of adult personality development. They try to pin down stages that all individuals go through in their adult lives. These theories do not adequately address individual variations in adult development. In an extensive study of a random sample of 500 men at midlife, it was concluded that there is extensive individual variation

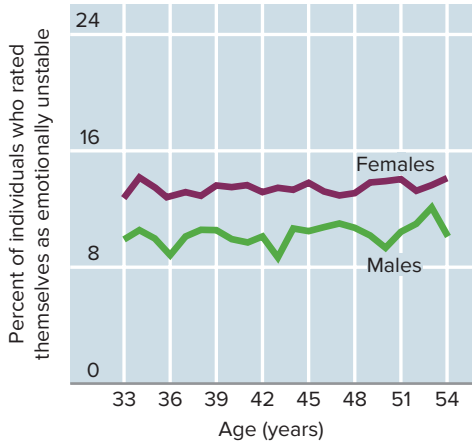

FIGURE 8

EMOTIONAL INSTABILITY AND AGE. In one longitudinal study, the emotional instability of individuals was assessed from age 33 to age 54 (McCrae & Costa, 1990). No significant increase in emotional instability occurred during middle age.

contemporary life-events approach The view that how a life event influences the individual's development depends not only on the event itself but also on mediating factors, the individual's adaptation to the life event, the life-stage context, and the sociohistorical context.

among men (Farrell & Rosenberg, 1981). In this view, middle-aged adults interpret, shape, alter, and give meaning to their lives (Arpanantikul, 2004). It also is important to recognize that some individuals may experience a midlife crisis in some contexts of their lives but not others (Lachman, 2004). Thus, turmoil and stress may characterize one area of a person's life (such as work) while things are going smoothly in another context (such as family).

Researchers have found that in one-third of the cases in which individuals have reported having a midlife crisis, the crisis is triggered by life events such as a job loss, financial problems, or illness (Wethington, Kessler, & Pixley, 2004). Let's further explore the role of life events in midlife development.

The Life-Events Approach

An alternative to the stage approach to adult development is the life-events approach (Chmitorz & others, 2021; Menke & others, 2021). In the early version of the life-events approach, life events were viewed as taxing circumstances for individuals, forcing them to change their personality (Holmes & Rahe, 1967). Events such as the death of a spouse, divorce, marriage, and so on were believed to involve varying degrees of stress, and therefore likely to influence the individual's development.

Today's life-events approach is more sophisticated (Fischer, Hagan, & Gotlib, 2021). The **contemporary life-events approach** emphasizes that how life events influence the individual's development depends not only on the event but also on *mediating factors* (physical health and family supports, for example), the individual's *adaptation to the life event* (appraisal of the threat and coping strategies, for example), the *life-stage context*, and the *sociohistorical context* (see Figure 9).

Consider how the life event of divorce might affect personality. A divorce is likely to be more stressful for individuals who are in poor health and have little family support. One individual may perceive it as highly stressful (less adaptive) rather than a challenge while another may develop coping strategies to effectively deal with it (more adaptive). And a divorce may be more stressful after many years of marriage when adults are in their fifties than when they have been married only a few years and are in their twenties (an example of life-stage context). Finally, adults may be able to cope more effectively with divorce today than several decades ago because divorce has become more commonplace and accepted in today's society (an example of sociohistorical context).

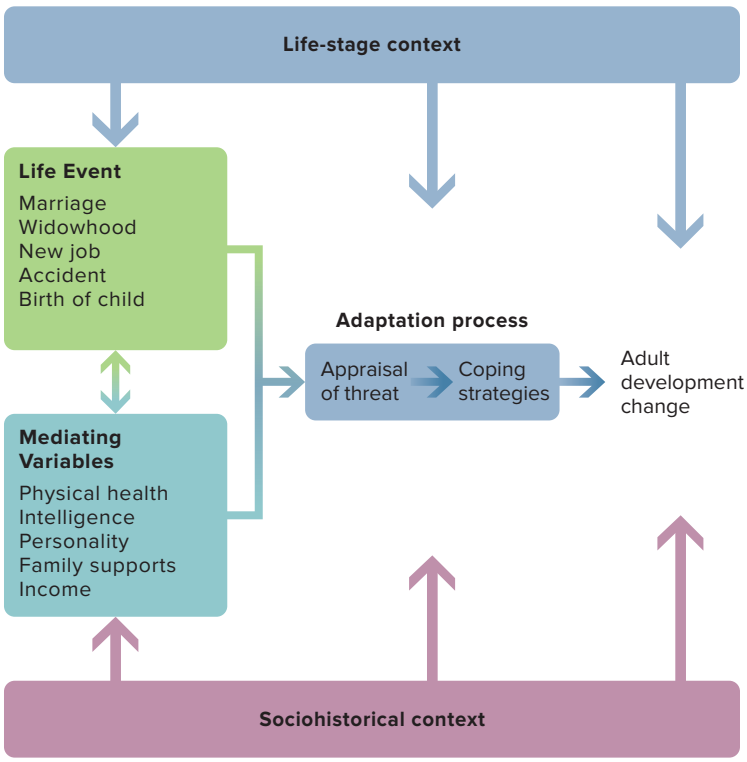

FIGURE **9**

A CONTEMPORARY LIFE-EVENTS FRAMEWORK FOR INTERPRETING ADULT DEVELOPMENTAL CHANGE. According to the contemporary life-events approach, the influence of a life event depends on the event itself, on mediating variables, on the life-stage and sociohistorical context, and on the individual's appraisal of the event and coping strategies.

Though the life-events approach is a valuable addition to understanding adult development, it has some drawbacks. One drawback is that the life-events approach places too much emphasis on change. It does not adequately recognize the stability that, at least to some degree, characterizes adult development. Another drawback is that it may not be life's major events that are the primary sources of stress, but our daily experiences (Bridges-Curry, Glenn, & Felton, 2021; Parker & others, 2020). Enduring a boring but tense job or living in poverty does not show up on scales of major life events. Yet the everyday pounding from these conditions can add up to a highly stressful life and eventually lead to illness (Gottschalk, Domschke, & Schiele, 2020). Greater insight into the source of life's stresses might come from focusing more on daily hassles and daily uplifts (Klusmann & others, 2021). Researchers have found that young and middle-aged adults experience a greater daily frequency of stressors than older individuals do (Almeida & Horn, 2004). Also, a recent study of college students found that daily hassles predicted subsequent health complaints (Tran & others, 2021). And a recent study revealed that older adults engaged in more proactive coping with minor hassles in their daily lives than younger adults did, and were better able to manage these problems before they become more stressful (Neubauer, Smyth, & Sliwinski, 2019).

Different kinds of stressors affect health in different ways—life events often produce prolonged arousal, whereas daily stressors are linked to spikes in arousal (Piazza & others, 2010).

Consider the effects of caring for a spouse who has Alzheimer disease. In this case, a life event (spouse diagnosed with an incurable disease) produces chronic stress for the caregiver, which also is linked to the daily stressors involved in caring for the individual.

GENERATIVITY

Erikson (1968) argues that middle-aged adults face the issue of **generativity versus stagnation,** which is the name Erikson gave to the seventh stage in his life-span theory. Generativity encompasses adults' desire to leave a legacy of themselves to the next generation (Homan, Greenberg, & Mailick, 2020; Moieni & others, 2021). By contrast, stagnation (sometimes called "self-absorption") develops when individuals sense that they have done nothing for the next generation.

Does research support Erikson's theory that generativity is an important dimension of middle age? Yes, it does (Stewart & Deaux, 2019). In George Vaillant's (2002) longitudinal studies of aging, generativity (defined in this study as "taking care of the next generation") in middle age was more strongly related than intimacy to whether individuals would have an enduring and happy marriage at 75 to 80 years of age. One participant in Vaillant's studies said, "From twenty to thirty I learned how to get along with my wife. From thirty to forty I learned how to be a success at my job, and at forty to fifty I worried less about myself and more about the children" (p. 114). An analysis of Vaillant's data found that achieving generativity was associated with better health in later life and a smoother adjustment to aging (Landes & others, 2014).

Other research also supports Erikson's (1968) view on the importance of generativity in middle age. In one study, Carol Ryff (1984) examined the views of women and men at different ages and found that middle-aged adults especially were concerned about generativity. In a longitudinal study of Smith College women, the desire for generativity increased as the participants aged from their thirties to their fifties (Stewart, Ostrove, & Helson, 2001) (see Figure 10). And in another study, generativity was strongly linked to middle-aged adults' positive social engagement in contexts such as family life and community activities (Cox & others, 2010). Further, in a recent study, a higher level of generativity in midlife was linked to greater wisdom in late adulthood (Ardelt, Gerlach, & Vaillant, 2018). And in a recent study, middle-aged and older adults were randomly assigned to either a 6-week generativity condition in which they wrote about life experiences and sharing advice with others or a control condition in which individuals wrote about neutral topics (Moieni & others, 2021). Those in the generativity condition with more positive expectations for mental health during aging reported greater perceived social support and lower levels of loneliness.

Middle-aged adults can develop generativity in a number of ways (Kotre, 1984). Through biological generativity, adults conceive and give birth to an infant. Through parental generativity, adults provide nurturance and guidance to children. Through work generativity, adults develop skills that are passed down to others. And through cultural generativity, adults create, renovate, or conserve some aspect of culture that ultimately survives.

Generativity
Feeling needed by people
Effort to ensure that young people get their chance to develop
Influence in my community or area of interest
A new level of productivity or effectiveness
Appreciation and awareness of older people
Having a wider perspective
Interest in things beyond my family

Identity certainty
A sense of being my own person
Excitement, turmoil, confusion about my impulses and potential (reversed)
Coming near the end of one road and not yet finding another (reversed)
Feeling my life is moving well
Searching for a sense of who I am (reversed)
Wishing I had a wider scope to my life (reversed)
Anxiety that I won't live up to opportunities (reversed)
Feeling secure and committed

FIGURE **10**

ITEMS USED TO ASSESS GENERATIVITY AND IDENTITY CERTAINTY. These items were used to assess generativity and identity certainty in the longitudinal study of Smith College women (Stewart, Ostrove, & Helson, 2001). In the assessment of identity certainty, five of the items involved reversed scoring. For example, if an individual scored high on the item "Searching for a sense of who I am," it was an indication of identity uncertainty rather than identity certainty.

STABILITY AND CHANGE

An important issue in life-span development is the extent to which individuals show stability in their development versus the extent to which they change. A number of longitudinal studies have assessed stability and change in the personalities of individuals at different points in their lives (Atherton, Donnellan, & Robins, 2021; Roberts and Nickel, 2020). A common finding is that in most cases, the less time between measurements of personality characteristics, the more stability they show. Thus, if we measure a person's introversion/extraversion at the age of 20 and then again at age 30, we are likely to find more stability than if we assess the person at age 20 and then at age 40.

Costa and McCrae's Baltimore Study Earlier we discussed the Big Five factors of personality as an important trait theory. Paul Costa and Robert McCrae (1998; McCrae, 2021) have studied the Big Five factors of approximately a thousand college-educated women and men from 20 to 96 years of age. Longitudinal data collection on people of varying ages began in the 1950s to the mid-1960s and is ongoing. Costa and McCrae found a great deal of stability across the adult years in the Big Five personality factors—openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism.

developmental **connection**

Life-Span Perspective

Erikson's early adulthood stage is intimacy versus isolation, and his late adulthood stage is integrity versus despair. Connect to "Introduction."

generativity versus stagnation The seventh stage in Erikson's life-span theory; it encompasses adults' desire to leave a legacy of themselves to the next generation.

However, more recent research indicates greater developmental changes in the Big Five personality factors in adulthood (Atherton, Donnellan, & Robins, 2021). For example, one study found that emotional stability, extraversion, openness, and agreeableness were lower in early adulthood, peaked between 40 and 60 years of age, and decreased in late adulthood, while conscientiousness showed a continuous increase from early adulthood to late adulthood (Specht, Egloff, & Schukle, 2011). Most research studies find that the greatest change occurs in early adulthood (Roberts & Nickel, 2020).

Berkeley Longitudinal Studies Most longitudinal studies indicate that neither extreme stability nor extreme change characterizes most people's personalities as they go through the adult years (Stewart & Deaux, 2019). One of the longest-running inquiries is the series of analyses called the Berkeley Longitudinal Studies. Initially, more than 500 children and their parents were studied in the late 1920s and early 1930s. The book *Present and Past in Middle Life* (Eichorn & others, 1981) profiles these individuals as they became middle-aged.

The results from early adolescence through a portion of midlife did not support either extreme in the debate over whether personality is characterized by stability or change. Some characteristics were more stable than others, however. The most stable characteristics were the degree to which individuals were intellectually oriented, self-confident, or open to new experiences. The characteristics that changed the most included the extent to which the individuals were nurturant or hostile and whether they had good self-control.

John Clausen (1993), one of the researchers in the Berkeley Longitudinal Studies, holds that too much attention has been given to discontinuities for all members of the human species, as exemplified in the adult stage theories. Rather, he stresses that some people experience recurrent crises and change a great deal over the life course, whereas others lead more stable, continuous lives and change far less.

What characterized the development of women in Ravenna Helson's Mills College Study?
Fuse/Corbis/Getty Images

Helson's Mills College Studies Another longitudinal investigation of adult personality development was conducted by Ravenna Helson and her colleagues (George, Helson, & John, 2011; Helson, 1997; Helson & Wink, 1992; Roberts, Helson, & Klohnen, 2002). They initially studied 132 women who were seniors at Mills College in California in the late 1950s. In 1981, when the women were 42 to 45 years old, they were studied again.

Helson and her colleagues distinguished three main groups among the Mills women: family-oriented (participants who had children), career-oriented (whether or not they also wanted families), and those who followed neither path (women without children who pursued only low-level work). Despite their different college profiles and their diverging life paths, the women in all three groups experienced some similar psychological changes over their adult years. However, the women in the third group changed less than those committed to career or family.

During their early forties, many of the women shared the concerns that stage theorists such as Levinson found in men: concern for young and old, introspectiveness, interest in roots, and awareness of limitations and death. However, the researchers in the Mills College Study concluded that rather than being in a midlife crisis, what the Mills women experienced was midlife *consciousness*. They also indicated that commitment to the tasks of early adulthood—whether to a career or family (or both)—helped women learn to control their impulses, develop interpersonal skills, become independent, and work hard to achieve goals. Women who did not commit themselves to one of these lifestyle patterns faced fewer challenges and did not develop as fully as the other women (Rosenfeld & Stark, 1987). In the Mills study, some women moved toward becoming "pillars of society" in their early forties to early fifties (Helson & Wink, 1992).

George Vaillant's Studies George Vaillant (2002) has conducted three longitudinal studies of adult development and aging: (1) a sample of 268 socially advantaged Harvard graduates born about 1920 (called the "Grant Study"); (2) a sample of 456 socially disadvantaged inner-city men born about 1930; and (3) a sample of 90 middle-SES, intellectually gifted women born about 1910. These individuals have been assessed numerous times (in most cases every two years), beginning in the 1920s to 1940s and continuing today for those still living. The main assessments involve extensive interviews with the participants, their parents, and teachers.

Vaillant categorized 75- to 80-year-olds as "happy-well," "sad-sick," or "dead." He used data collected from these individuals when they were 50 years of age to predict which categories

At age 55, actor Jack Nicholson said, "I feel exactly the same as I've always felt: a slightly reined-in voracious beast." Nicholson felt his personality had not changed much. Some others might think they have changed more. *How much does personality change and how does it stay the same through adulthood?*

FIGURE **11**

LINKS BETWEEN CHARACTERISTICS AT AGE 50 AND HEALTH AND HAPPINESS AT AGE 75 TO 80. In a longitudinal study, the characteristics shown above at age 50 were related to whether individuals were happy-well, sad-sick, or dead at age 75 to 80 (Vaillant, 2002).

they were likely to end up in at 75 to 80 years of age. Alcohol abuse and smoking at age 50 were the best predictors of which individuals would be dead at 75 to 80 years of age. Other factors at age 50 were linked with being in the "happy-well" category at 75 to 80 years of age: getting regular exercise; avoiding being overweight; being well educated; having a stable marriage; being future-oriented; being thankful and forgiving; empathizing with others; being active with other people; and having good coping skills. Wealth and income at age 50 were not linked with being in the "happy-well" category at 75 to 80 years of age. The results for one of Vaillant's studies, the Grant Study of Harvard men, are shown in Figure 11.

Conclusions What can we conclude about stability and change in personality development during the adult years? People show more stability in their personality when they reach midlife than they did when they were younger adults (Atherton, Donnellan, & Robins, 2021). These findings support what is called a *cumulative personality model of personality development*, which states that with time and age people become more adept at interacting with their environment in ways that promote increased stability in personality (Caspi & Roberts, 2001).

This does not mean that change is absent throughout middle and late adulthood (Ayoub & Roberts, 2018). Ample evidence shows that social contexts, new experiences, and sociohistorical changes can affect personality development, but the changes in middle and late adulthood are usually not as great as in early adulthood (Mroczek, Spiro, & Griffin, 2006). In general, changes in personality traits across adulthood also occur in a positive direction (Roberts & Nickel, 2020). Such positive changes equate with becoming more socially mature.

In sum, recent research contradicts the old view that stability in personality begins to set in at about 30 years of age (Atherton, Donnellan, & Robins, 2021; Roberts & Nickel, 2020). Although there are some consistent developmental changes in the personality traits of large numbers of people, at the individual level people can show unique patterns of personality traits, and these patterns often reflect life experiences related to themes of their specific developmental period. For example, researchers have found that individuals who are in a stable marriage and a solid career track become more socially dominant, conscientious, and emotionally stable as they go through early adulthood (Roberts & Wood, 2006). And, for some of these individuals, there is greater change in their personality traits than for other individuals (Roberts & Nickel, 2020).

LG3 Describe personality and its development in adulthood.

Review

- What are trait theories? What are the Big Five factors of personality?
- What are some views of adult development of personality?
- What is Erikson's view of middle-aged adults?
- What are some major longitudinal studies of adult personality development, and what implications do they have for the stability/change issue?

Connect

- This section discussed four different longitudinal studies. What are the pros and cons of using a longitudinal study to collect data?

Reflect *Your Own Personal Journey of Life*

- Think about the Big Five factors of personality for a few moments. Using the Big Five factors, describe your own personality.

reach your **learning goals**

The Self, Identity, and Personality

1 The Self

LG1 Discuss the main ways the self and understanding others are conceptualized and how they develop.

Self-Understanding and Understanding Others

- Self-understanding is the cognitive representation of the self, the substance of self-conceptions. Developmental changes in self-understanding include the construction of the self in infancy in terms of self-recognition and transformations in self-understanding in childhood (including perspective taking).
- Self-understanding in early childhood is characterized by confusion of self, mind, and body; concrete, physical, and active descriptions; and unrealistic positive overestimations. Young children display more sophisticated self-understanding and understanding of others than was previously thought.
- Self-understanding in middle and late childhood involves an increase in the use of psychological characteristics and traits, social descriptions, and social comparison; distinction between the real and ideal self; and an increase in realistic self-evaluations. Social understanding also increases in middle and late childhood, especially in taking the perspectives of others.
- Self-definition in adolescence is more abstract and idealistic, involves more contradictions within the self, is more fluctuating, includes concern about the real self versus the ideal self, is characterized by increased self-consciousness, and is more integrative. Increases in social understanding in adolescence involve greater skepticism of others' reports of their traits, more in-depth perspective taking, and social cognitive monitoring. Developments in adults' self-understanding include expanded self-awareness, revision of possible selves, and life reviews of older adults.

Self-Esteem and Self-Concept

- Self-esteem refers to global evaluations of the self; it is also called self-worth and self-image. Self-concept consists of domain-specific evaluations of the self. Self-esteem can change over time, and low self-esteem is linked with depression.
- The accuracy of self-evaluations increases across the elementary school years. Some studies have found that self-esteem decreases in adolescence, but overall, most adolescents still have positive self-esteem. Important aspects of self-esteem include the degree to which it is linked to performance. This varies, as there are only moderate correlations with school performance and varying correlations with job performance; individuals with high self-esteem have greater initiative and this can produce positive or negative outcomes.

- Self-esteem is strongly correlated with happiness, but there is a dark side to high self-esteem in that some individuals who have high self-esteem are conceited and narcissistic. Five ways to increase self-esteem are through (1) identifying the causes of low self-esteem and the domains of competence important to the self, (2) providing emotional support and social approval, (3) taking responsibility for one's own self-esteem, (4) achieving goals, and (5) developing effective coping strategies.

Self-Regulation

- Self-regulation involves the ability to control one's behavior without having to rely on others for help. Two-year-olds may show rudimentary forms of self-regulation, but many preschoolers show increased self-regulation. Elementary-school-aged children increase their self-regulation. In adolescence, some changes may increase self-regulation, while others decrease it. Self-control increases in early and middle adulthood.
- Self-regulation may vary by domain. For example, older adults often show less self-regulation in the physical domain than younger adults do. Baltes proposed the selective optimization with compensation theory of self-regulation. Many older adults show a remarkable ability to engage in self-regulation despite encountering losses.

2 Identity

LG2 Explain the key facets of identity development.

What Is Identity?

- Identity is a self-portrait with many pieces, including vocational/career identity, political identity, religious identity, relationship identity, gender identity, and cultural/ethnic identity.

Erikson's View

- Identity versus identity confusion is Erikson's fifth developmental stage, which individuals experience during the adolescent years. At this time, adolescents examine who they are, what they are all about, and where they are going in life. Erikson describes the psychosocial moratorium between childhood dependence and adult independence that adolescents experience, which promotes identity exploration.

Some Contemporary Thoughts on Identity

- In the contemporary view, identity development is more gradual than Erikson's term *crisis* implies, is extraordinarily complex, neither begins nor ends with adolescence, and emphasizes multiple identities.

Developmental Changes

- According to Marcia, various combinations of crisis and commitment produce four identity statuses: identity diffused, identity foreclosed, identity moratorium, and identity achieved. A number of experts stress that the key developmental changes in identity occur in the late teens and early twenties. "MAMA" (moratorium-achievement-moratorium-achievement) cycles may continue throughout adulthood. Criticisms of Marcia's approach have been made, especially that identity exploration and commitment need to be examined more in depth and on a continuing basis.

Identity and Social Contexts

- Adolescents' identity development advances when their relationship with their parents includes both individuality and connectedness. Friendships, romantic relationships, and the digital environment influence adolescents' identity development.
- Cross-cultural variations in identity occur. Ethnic identity may present special issues for members of ethnic minority groups, and they may confront these issues for the first time in adolescence. A positive ethnic identity is increasingly linked to positive outcomes for ethnic minority adolescents. There also has been increasing interest in racial identity as well as a unified concept of ethnic-racial identity.

3 Personality

LG3 Describe personality and its development in adulthood.

Trait Theories and the Big Five Factors of Personality

- Trait theories state that personality consists of broad dispositions, called traits, that tend to produce characteristic responses. One trait theory that has received considerable attention involves the Big Five factors of personality, which consist of openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism. Also, optimism is linked with a number of positive developmental outcomes, including better health and increased longevity. Today most psychologists stress that personality is a product of trait-situation interaction.

Views on Adult Personality Development

- Two of the important adult developmental views are the stage-crisis view and the life-events approach. Levinson's and Erikson's theories are stage-crisis views. Midlife crises are not nearly as common as the stereotype suggests. What does arise is a midlife consciousness that focuses on such matters as how to adapt to aging. The life-events approach argues that life events and how people adapt to them are important in understanding adult development. There is considerable variation in how people go through the adult stages of development and in how they experience and adapt to life events.

Generativity

- Erikson argues that middle-aged adults face a significant issue in life—generativity versus stagnation—which is the name he gave to the seventh stage in his life-span theory. Generativity encompasses adults' desire to leave a legacy of themselves to the next generation.

Stability and Change

- Four longitudinal studies that have addressed stability and change in adult development are Costa and McCrae's Baltimore Study, the Berkeley Longitudinal Studies, Helson's Mills College Study, and Vaillant's studies. The longitudinal studies have shown both stability and change in adult personality development. The cumulative personality model states that with time and age personality becomes more stable.
- Change in personality traits occurs more in early adulthood than middle and late adulthood, but a number of aspects of personality do continue to change after early adulthood. Change in personality traits across adulthood occurs in a positive direction, reflecting social maturity. At the individual level, changes in personality are often linked to life experiences related to a specific developmental period. Some people change more than others.

chapter 12

GENDER AND SEXUALITY

chapter **outline**

1 Biological, Social, and Cognitive Influences on Gender

Learning Goal 1 Explain biological, social, and cognitive influences on gender.

Biological Influences
Social Influences
Cognitive Influences

2 Gender Stereotypes, Similarities, Differences, and Classification

Learning Goal 2 Discuss gender stereotypes, similarities, differences, and classification.

Gender Stereotyping
Sex and Gender Similarities and Differences
Gender-Role Classification
Going Beyond Gender as Binary

3 Gender Development Through the Life Span

Learning Goal 3 Describe the development of gender through the life span.

Childhood
Adolescence
Adulthood and Aging

4 Exploring Sexuality

Learning Goal 4 Characterize influences on sexuality, the nature of sexual orientation, and some sexual problems.

Biological and Cultural Factors
Sexual Orientation
Sexually Transmitted Infections
Forcible Sexual Behavior and Sexual Harassment

5 Sexuality Through the Life Span

Learning Goal 5 Summarize how sexuality develops through the life span.

Childhood
Adolescence and Emerging Adulthood
Adult Development and Aging

preview

Human beings are involved in the existence and continuation of life. The topics of this chapter—gender and sexuality—are central aspects of human development.

1 Biological, Social, and Cognitive Influences on Gender

LG1 Explain biological, social, and cognitive influences on gender.

Biological Influences | Social Influences | Cognitive Influences

Gender refers to characteristics related to femininity and masculinity based on social and cultural norms. **Gender identity** involves a sense of one's own gender, including knowledge, understanding, and acceptance of being a boy/man, girl/woman, or another gender (Erickson-Schroth & Davis, 2021). **Gender roles** are sets of expectations that prescribe how boys/men and girls/women should think, act, and feel (Best & Puzio, 2019). During the preschool years, most children increasingly act in ways that match their culture's gender roles. **Gender-typing** refers to acquisition of a traditional masculine or feminine role. For example, fighting is more characteristic of a traditional masculine role and crying is more characteristic of a traditional feminine role (Helgeson, 2020).

As just mentioned, gender identity involves knowing whether you are a boy, a girl, or another gender. Until recently, it was thought that this aspect of gender identity emerged at about 2½ years of age. However, a longitudinal study that explored the acquisition of gender labels in infancy and their implications for gender-typed play revealed that gender identity likely emerges before children are 2 years old (Zosuls & others, 2009). In this study, infants began using gender labels on average at 19 months of age, with girls beginning to use gender labels earlier than boys. This gender difference emerged at 17 months and increased at 21 months. Use of gender labels was linked to gender-typed play, suggesting that knowledge of gender categories may affect gender-typing earlier than age 2 years.

developmental **connection**

Biological Processes

Hormones are powerful chemical substances secreted by the endocrine glands and carried through the body by the bloodstream. Connect to "Physical Development and Biological Aging."

gender Characteristics related to femininity and masculinity based on social and cultural norms.

gender identity Involves a sense of one's own gender, including knowledge, understanding, and acceptance of being a boy/man, girl/woman, or another gender.

gender role A set of expectations that prescribe how girls/women or boys/men should think, act, or feel.

gender-typing Acquisition of a traditional masculine or feminine role.

estrogens A class of sex hormones—an important one of which is estradiol—that primarily influences the development of female sex characteristics and helps to regulate the menstrual cycle.

androgens A class of sex hormones—an important one of which is testosterone—that primarily promotes the development of male genitals and secondary sex characteristics.

BIOLOGICAL INFLUENCES

It was not until the 1920s that researchers confirmed the existence of human sex chromosomes, the genetic material that determines our sex. Humans normally have 46 chromosomes, arranged in pairs. A 23rd pair with two X-shaped chromosomes produces a female. A 23rd pair with an X chromosome and a Y chromosome produces a male.

Hormones

The two classes of hormones that have the most influence on sex are estrogens and androgens. Both estrogens and androgens occur in females and males, but in very different concentrations–typically based on the sex they were assigned at birth (female or male).

Estrogens primarily influence the development of female physical sex characteristics and help regulate the menstrual cycle. Estrogens are a general class of hormones. An example of an important estrogen is estradiol. In females, estrogens are produced mainly by the ovaries.

Androgens primarily promote the development of male genitals and secondary sex characteristics. One important androgen is testosterone. Androgens are produced by the adrenal glands in males and females, and by the testes in males.

During the first few weeks of gestation, female and male embryos look alike (Aatsha & Krishan, 2020). Male sex organs start to differ from female sex organs when a gene on the Y chromosome directs a small piece of tissue in the embryo to turn into testes. Once the testes have formed, they begin to secrete testosterone. In females there is no Y chromosome, and the tissue turns into ovaries. To explore biological influences on gender, researchers have studied individuals who are exposed to unusual levels of sex hormones early in development (Ostatnikova & others, 2021).

Although sex hormones alone do not dictate behavior, researchers have found links between sex hormone levels and certain behaviors (Vosberg & others, 2021). The most established effects of testosterone on humans involve aggressive behavior and sexual behavior (Nguyen, 2018). Levels of testosterone are correlated with sexual behavior among individuals assigned male during puberty and adulthood (Kruger & others, 2019). One study revealed that a higher fetal testosterone level measured from amniotic fluid was linked to increased traditional masculine play, such as increased aggression, in 6- to 10-year-old boys and girls (Auyeung & others, 2009). Further, in a recent study, 3-year-old boys with higher prenatal testosterone levels had shorter delay of gratification times and more attention problems (Korner & others, 2019). And in recent research with 18-month-olds, in contrast to mothers, fathers' higher testosterone levels were linked to increased child maltreatment, more negative parenting, and less positive parenting (Rodriguez, Granger, & Leerkes, 2021).

The Evolutionary Psychology View Evolutionary psychology emphasizes that adaptation during the evolution of humans produced psychological differences between men and women (Buss, 2019). Evolutionary psychologists argue that primarily because of their differing roles in reproduction, men and women faced different pressures in primeval environments when the human species was evolving (Palmer-Hague, 2020; Thoni, Volk, & Cortina, 2021). In particular, because having multiple sexual liaisons improves the likelihood that men will pass on their genes, natural selection favored men who adopted short-term mating strategies. These men competed with other men to acquire more resources in order to access females. Therefore, say evolutionary psychologists, men evolved dispositions that favor violence, competition, and risk taking (Lewis, Al-Shawaf, & Buss, 2021).

In contrast, according to evolutionary psychologists, women's contributions to the gene pool were improved by securing resources for their offspring—an objective that they achieved by obtaining long-term mates who could support a family. As a consequence, natural selection favored women who devoted effort to parenting and chose mates who could provide their offspring with resources and protection. Women developed preferences for successful, ambitious men who could provide these resources (Buss, 2019).

Critics of evolutionary psychology argue that its hypotheses are backed by speculations about prehistory, not evidence, and that in any event people are not locked into behavior that was adaptive in the evolutionary past. Critics also claim that the evolutionary view pays little attention to cultural and individual variations in gender differences (Gangestad & Chang, 2020).

SOCIAL INFLUENCES

Many social scientists do not locate the cause of psychological gender differences in biological dispositions. Rather, they argue that these differences can be traced to social experiences (Pang & Baumann, 2020). Three theories that reflect this view have been influential.

Alice Eagly (2016, 2018) proposed **social role theory,** which states that psychological gender differences result from the contrasting roles of women and men. In most cultures around the world, women have less power and status than men do, and they control fewer resources (UNICEF, 2020). Compared with men, women perform more domestic work, spend fewer hours in paid employment, receive lower pay, and are more thinly represented in the highest levels of organizations. In Eagly's view, as women adapted to roles with less power and less status in society, they showed more cooperative, less dominant profiles than men. Thus, the social hierarchy and division of labor are important causes of gender differences in power, assertiveness, and nurture (Eagly, 2018).

The **psychoanalytic theory of gender** stems from Sigmund Freud's view that the preschool child develops a sexual attraction to the opposite-sex parent. At 5 or 6 years of age, the child renounces this attraction because of anxious feelings. Subsequently, the child identifies with the same-sex parent, unconsciously adopting the same-sex parent's characteristics. However, developmentalists do not hold that gender development proceeds as Freud proposed. Children become gender-typed much earlier than 5 or 6 years of age, and they become masculine or feminine even when a same-sex parent is not present in the family.

The *social cognitive approach* provides an alternative explanation of how children develop gender-typed behavior (see Figure 1). According to the **social cognitive theory of gender,**

developmental **connection**
Biological Processes
The genetic difference in males and females occurs in the 23rd pair of chromosomes: the male's Y chromosome is smaller than the female's X chromosome. Connect to "Biological Beginnings."

developmental **connection**
Biological Processes
Evolutionary psychology emphasizes the importance of adaptation, reproduction, and "survival of the fittest" in shaping behavior. Connect to "Biological Beginnings."

Gender differences are adaptations to the differing restrictions and opportunities that a society provides for its men and women.

—ALICE EAGLY
Contemporary Psychologist, Northwestern University

developmental **connection**
Social Cognitive Theory
Social cognitive theory holds that behavior, environment, and person (cognitive) factors are the key aspects of development. Connect to "Introduction."

social role theory Eagly's theory that psychological gender differences are caused by the contrasting social roles of women and men.

psychoanalytic theory of gender Theory that stems from Freud's view that preschool children develop a sexual attraction to the opposite-gender parent, then at 5 or 6 years of age renounce the attraction because of anxious feelings, subsequently identifying with the same-gender parent and unconsciously adopting the same-gender parent's characteristics.

social cognitive theory of gender The idea that children's gender development occurs through observation and imitation of gender behavior as well as through the rewards and punishments children experience for behaviors believed to be appropriate or inappropriate for their gender.

FIGURE 1
PARENTS INFLUENCE THEIR CHILDREN'S GENDER DEVELOPMENT BY ACTION AND EXAMPLE.

Theory	Processes	Outcome
Psychoanalytic theory	Sexual attraction to opposite-sex parent at 3 to 5 years of age; anxiety about sexual attraction and subsequent identification with same-sex parent at 5 to 6 years of age	Gender behavior similar to that of same-sex parent
Social cognitive theory	Rewards and punishments of gender-appropriate and -inappropriate behavior by adults and peers; observation and imitation of models' masculine and feminine behavior	Gender behavior

children's gender development occurs through observation and imitation, and through the rewards and punishments children experience for gender-appropriate and gender-inappropriate behavior (Bussey & Bandura, 1999; Leaper & Bigler, 2018).

Parents Parents, by action and example, influence their children's and adolescents' gender development (Erickson-Schroth & Davis, 2021). Parents often use rewards and punishments to teach their daughters to be feminine ("Karen, you are being a good girl when you play gently with your doll") and their sons to be masculine ("Keith, a big boy like you is not supposed to cry").

Mothers and fathers often interact differently with their children and adolescents (Leaper & Bigler, 2018). Mothers are more involved with their children and adolescents than are fathers, although fathers increase the time they spend in parenting when they have sons, and parents are less likely to become divorced when they have sons (Galambos, Berenbaum, & McHale, 2009). Mothers' interactions with their children and adolescents often center on caregiving and teaching activities, whereas fathers' interactions often involve leisure activities (Galambos, Berenbaum, & McHale, 2009). Parents frequently interact differently with sons and daughters, and these gendered interactions that begin in infancy usually continue through childhood and adolescence (Morawska, 2020). A recent study of 15- to 39-month-olds found that mothers tended to protect young children from distress while fathers were more likely to assist them in coping with frustration (Deichmann & Ahnert, 2021).

In reviewing research on maternal and paternal parenting strategies, Phyllis Bronstein (2006) reached these conclusions:

- *Mothers' socialization strategies*. In many cultures, mothers socialize their daughters to be more obedient and responsible than their sons. They also place more restrictions on daughters' autonomy.
- *Fathers' socialization strategies*. Fathers pay more attention to sons than to daughters, engage in more activities with sons, and put forth more effort to promote sons' intellectual development.

Thus, according to Bronstein (2006, pp. 269–270), "Despite an increased awareness in the United States and other Western cultures of the detrimental effects of gender stereotyping, many parents continue to foster behaviors and perceptions that are consonant with traditional gender role norms."

Other Adults, Media, and Peers Children also learn about gender from observing other adults in the neighborhood and in the media (Xie & others, 2020). As children get older, peers become increasingly important (McGuire, Jefferys, & Rutland, 2020). Peers extensively reward and punish gender behavior (Leaper & Bigler, 2018). For example, when children play in gender-stereotypical ways that are deemed culturally appropriate, they tend to be rewarded by their peers (Nabbijohn & others, 2020). Those who engage in activities that are considered inappropriate for their gender tend to be criticized or abandoned by their peers. It is generally more accepted for girls to act like boys than for boys to act like girls; thus, use of the term *tomboy* to describe masculine girls is often thought of as less derogatory than the term *sissy* to describe feminine boys (Pasterski, Golombok, & Hines, 2011).

In a recent study of 4- to 9-year-olds, gender-conforming children whose behavior was consistent with the expectations for their gender were perceived more positively than gender-nonconforming children whose behavior was inconsistent with the expectations for their gender (Kwan & others, 2020). Also in this study, children expressed more negative perceptions of gender-nonconforming boys than gender-nonconforming girls. Further, in another study of 9- to 10-year-olds in Great Britain, gender-nonconforming boys were at highest risk for peer rejection (Braun & Davidson, 2017). In this study, gender-nonconforming girls were preferred more than gender-conforming girls, with children most often citing masculine activities as the reason for this choice. Also, a recent study of 3- to 4-year-olds and 6- to 7-year-olds found that boys were more likely to engage in gender stereotyping, especially with masculine stimuli such as toys, and to be sanctioned for not conforming to gender stereotypes (Skocajic & others, 2020). In addition, gender stereotyping was more prevalent in 6- to 7-year-olds than in 3- to 4-year-olds. And in recent research, young male adolescents felt more pressure from parents to engage in gender-conforming behavior and felt more pressure from peers to avoid engaging in gender-nonconforming behavior (Jackson, Bussey, & Myers, 2021).

From 4 to about 12 years of age, children spend a large majority of their free play time exclusively with others of their own gender (Maccoby, 2002). What kind of socialization takes place in these same-gender play groups? In one study, researchers observed preschoolers over a period of six months (Martin & Fabes, 2001). The more time boys spent interacting with other boys, the higher their activity level, engagement in rough-and-tumble play, and preference for gender-typed toys and games, and the less time they spent near adults. By contrast, the more time girls spent interacting with other girls, the lower their levels of activity and aggression, the higher their engagement in gender-typed play activities, and the more time they spent near adults. A study of preschool children (average age: 4 years) found that children selected playmates of the same gender who engaged in similar levels of gender-typed activities (Martin & others, 2013). In selecting a playmate, comparisons of gender of child and activity revealed that gender of the playmate was more important than activity. After watching elementary school children repeatedly play in same-gender groups, two researchers characterized the playground as "gender school" (Luria & Herzog, 1985). From adolescence through late adulthood, friendships also mainly consist of same-gender peers (Mehta & Strough, 2009, 2010).

COGNITIVE INFLUENCES

Observation, imitation, rewards, and punishment—these are the mechanisms by which gender develops, according to social cognitive theory. Interactions between the child and the social environment are viewed as the main keys to gender development. Some critics who adopt a cognitive approach argue that social cognitive explanations pay too little attention to the child's own mind and understanding, portraying the child as passively acquiring gender roles (Martin, Ruble, & Szkrybalo, 2002).

One influential cognitive theory is **gender schema theory,** which states that gender-typing emerges as children gradually develop gender schemas of what is gender-appropriate and gender-inappropriate in their culture (Martin & others, 2017). A *schema* is a cognitive structure, a network of associations that guide an individual's perceptions. A *gender schema* organizes the world into categories of girls/women and boys/men. Children are internally motivated to perceive the world and to act in accordance with their developing schemas. Bit by bit, children pick up what is gender-appropriate and gender-inappropriate in their culture, using this information to develop gender schemas that shape how they perceive the world and what they remember (Conry-Murray, Kim, & Turiel, 2012). Children are motivated to act in ways that conform to these gender schemas. Thus, gender schemas fuel gender-typing.

What concepts might preschool children already have in place regarding gender-appropriate occupations? To read about this link, see the *Connecting with Research* interlude.

In sum, cognitive factors contribute to the way children think and act as boys/men and girls/women. Through biological, social, and cognitive processes, children develop their gender attitudes and behaviors (Erickson-Schroth & Davis, 2021).

gender schema theory The theory that gender-typing emerges as children gradually develop gender schemas of what is gender-appropriate and gender-inappropriate in their culture.

connecting with research

What Do Preschool Children Think about Gender and Occupations?

Courtesy of Emily Coyle

Emily Coyle
Key Points:
- gender role development
- schema development
- STEM learning

Researcher Emily Coyle explores the ways early play experiences shape children's later interests in science, technology, engineering, and mathematics (STEM) occupations. In one of her studies, 62 preschool girls were given the opportunity to play a computer game about occupations (Coyle & Liben, 2016). The game was designed to help observers understand the ways gender schemas influence future career choices. Many studies have explored broader societal influences, such as media influences on children's gender-related thoughts and behaviors. This study explored the ways children's personal sensitivity to gender roles affects their expectations for later career options.

The research was conducted in two steps. In the first step, each preschool girl was presented with tasks designed to determine how focused she was on gender in different situations. This step revealed how influential a girl's gender schema was in her decision-making processes.

In the second step, which took place two weeks later, the preschool girls played a computer game that depicted dolls performing 12 jobs:

- 4 traditionally feminine: librarian, teacher, nurse, florist
- 4 traditionally masculine: explorer, astronaut, firefighter, chemist
- 4 novel jobs created for this game: benster, hegist, silter, tenic

There was an important variation in the dolls performing the jobs. Some preschool girls played the game featuring a doll that was a hyper-feminized Barbie doll, while others played the game with a female doll with the same skin tone, hair color, and hair style, but with an unexaggerated body shape. Of special interest was the effects of watching the hyper-feminine Barbie doll participating in traditionally male jobs.

After the second step was completed, the girls were asked about their interest in the jobs featured in the game, and then about traditionally masculine and feminine occupations that were not in the computer game.

The results indicated that the preschool girls who were highly sensitive to gender in the first step of the study focused on the hyper-feminized Barbie doll when the doll was in traditionally feminine jobs. Results showed that these girls ended the study even more interested in traditionally feminine occupations. The preschool girls who were less sensitive to gender in the first step of the study showed no change in occupational interests. Thus, the general strategy of showing girls highly stereotypical-looking women in traditional masculine roles may be ineffective in encouraging preschool girls to consider traditionally masculine occupations. This research also shows the importance of considering individual characteristics, such as sensitivity to gender roles, when designing strategies to attract girls into STEM occupations.

What activities might a preschool teacher develop to encourage both female and male children to consider a wide range of occupations?

2 Gender Stereotypes, Similarities, Differences, and Classification

LG2 Discuss gender stereotypes, similarities, differences, and classification.

Gender Stereotyping | Sex and Gender Similarities and Differences | Gender-Role Classification | Going Beyond Gender as Binary

To what extent do real behavioral differences exist between boys/men and girls/women? Are many of the reported differences just stereotypes? What are some different categories of gender classification? Is it time to go beyond the concept of gender as binary?

First imagine that this is a photograph of a baby girl. *What expectations would you have for her?* Then imagine that this is a photograph of a baby boy. *What expectations would you have for him?*
Kwame Zikomo/Purestock/SuperStock

GENDER STEREOTYPING

Gender stereotypes are general impressions and beliefs about girls/women and boys/men. For example, men are powerful; women are weak. Men make good physicians; women make good nurses. Men are good with numbers; women are good with words. Women are emotional; men are not. All of these are stereotypes. They are generalizations about a group that reflect widely held beliefs. Stereotypes may or may not reflect how women and men actually think and behave. Recent research has found that gender stereotypes are, to a great extent, still present in today's world, in the lives of both children and adults (Helgeson, 2020). Researchers also have found that boys' gender stereotypes are more rigid than girls' (Halim, 2016).

As people go through the human lifespan, categories such as gender and ethnicity intersect and can create systems of power and privilege as well as oppression and discrimination. For example, higher-socioeconomic-status non-Latinx White males have experienced considerably greater privilege and less discrimination than African American females.

SEX AND GENDER SIMILARITIES AND DIFFERENCES

What is the reality behind gender stereotypes? Let's examine some of the differences between sex and gender groups, keeping the following information in mind:

- The differences are averages and do not apply to all girls/women or all boys/men.
- Even when gender differences occur, there often is considerable overlap between boys/men and girls/women.
- The majority of the research that has been conducted on sex and gender similarities and differences has assumed that participants are cisgender (i.e., that they have a gender identity that matches their assigned sex at birth).
- The differences may be due primarily to biological factors, sociocultural factors, or both.

First, we examine physical similarities and differences, and then we turn to cognitive and socioemotional similarities and differences.

Physical Similarities and Differences We could devote pages to describing physical differences between the average male and the average female. For example, females have about twice the body fat of males, most of it concentrated around breasts and hips. In males, fat is more likely to go to the abdomen. On average, males grow to be 10 percent taller than females. Androgens (the "male" hormones) promote the growth of long bones; estrogens (the "female" hormones) stop such growth at puberty.

Many physical differences between males and females are tied to health. From conception onward, females have a longer life expectancy than males, and females are less likely than males to develop physical or mental disorders. Females are more resistant to infection, and their blood vessels are more elastic than those of males. Males have higher levels of stress hormones, which cause faster clotting and higher blood pressure.

Just how much does sex matter when it comes to brain structure and activity? Brain differences that have been discovered include the following:

- One part of the hypothalamus that is involved in sexual behavior tends to be larger in males than in females (Swaab & others, 2001).

gender stereotypes General impressions and beliefs about girls/women and boys/men.

- An area of the parietal lobe that functions in visuospatial skills tends to be larger in males than in females (Frederikse & others, 2000).
- The areas of the brain involved in emotional expression tend to show more metabolic activity in females than in males (Gur & others, 1995).
- Female brains are approximately 10 percent smaller than male brains (Giedd & others, 2012). However, female brains have more folds; the larger folds (called convolutions) allow more surface brain tissue within the skulls of females than males (Luders & others, 2004).

Although sex differences in brain structure and function have been found, many of these differences are small or research results are inconsistent regarding the differences (Grabowska, 2020; Wiersch & Weis, 2021). Recently, because the distributions for males and females on different brain features overlap considerably, Janet Shibley Hyde and her colleagues (2019) have concluded that in most instances it is more accurate to describe these features as a mosaic rather than as male-typical and female-typical brains. Also, when gender differences in the brain have been detected, in many cases they have not been directly linked to psychological differences (Grabowska, 2020). In addition, similarities and differences in the brains of males and females may be due to biological or experiential factors (Hyde & others, 2019).

Cognition and Achievement No gender differences occur in overall intellectual ability, but in some cognitive and achievement areas gender differences do appear (Berkowitz & others, 2020; Halpern, Flores-Mendoza, & Rindermann, 2020). Some gender experts, such as Janet Shibley Hyde (Hyde & others, 2019), stress that the cognitive differences between girls/women and boys/men have been exaggerated. For example, Hyde points out that there usually is considerable overlap in the distributions of scores between gender groups on visuospatial tasks (see Figure 2). However, some researchers have found that boys/men have better visuospatial skills than girls/women (Halpern, 2012). Despite equal participation in the National Geography Bee, in most years all 10 finalists have been boys (Liben, 1995). Also, a research review concluded that boys have better visuospatial skills than girls (Halpern, Flores-Mendoza, & Rinderman, 2020).

Are there gender differences in math ability? A very large-scale study of more than 7 million U.S. students in grades 2 through 11 revealed no differences in math scores for boys and girls (Hyde & others, 2008). And a research meta-analysis found no gender differences in math scores for adolescents (Lindberg & others, 2010). Further, in the National Assessment of Educational Progress (2019a) there were virtually no gender differences in math scores at the fourth-grade level, with boys scoring only 3 points higher (242) than girls (239) on a 500-point scale.

Despite the similarities in math achievement scores for boys and girls, a research review concluded that girls have more negative math attitudes and that parents' and teachers' expectations for children's math competence are often gender-biased in favor of boys (Gunderson & others, 2012). Also, in one study, 6- to 12-year-olds reported that math is mainly for boys (Cvencek, Meltzoff, & Greenwald, 2011). And in a recent study of 14- to 18-year-olds, believing in innate math ability was associated with lower self-perceived ability and intrinsic motivation in girls but not boys (Heyder, Weidinger, & Steinmayr, 2021).

Are there gender differences in reading and writing skills? There is strong evidence that girls/women outperform boys/men in reading and writing. In the most recent National Assessment of Educational Progress (2019b) report, girls had higher reading achievement than boys in both fourth- and eighth-grade assessments, with girls 11 points higher (269) than boys (258) in the eighth grade. Girls also have consistently outperformed boys in writing skills in the National Assessment of Educational Progress in fourth-, eighth-, and twelfth-grade assessments. Further, in a recent study of preschool children, gender differences favored girls for a broad range of pre-academic and cognitive skills, including attention, language, and literacy (Brandlistuen & others, 2021).

With regard to school achievement, girls earn better grades and complete high school at a higher rate than boys (Berkowitz & others, 2020). Boys are more likely than girls to be assigned to special/remedial education classes. Girls are more likely than boys to be engaged with academic material and to be attentive in class, and they tend to put forth more academic effort and participate more in class (DeZolt & Hull, 2001).

Keep in mind that measures of achievement in school or scores on standardized tests may reflect many factors besides cognitive ability. For example, performance in school may in part reflect attempts to conform to gender roles or differences in motivation, self-regulation, or other socioemotional characteristics (Pang & Baumann, 2020). For example, a recent large-scale

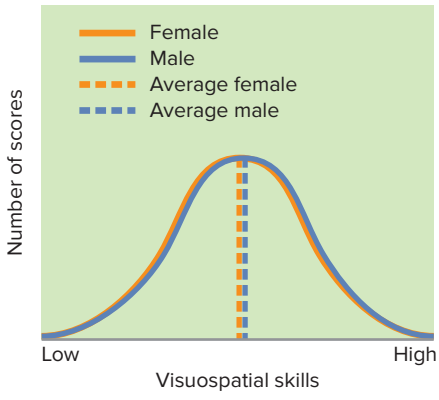

FIGURE 2

VISUOSPATIAL SKILLS OF BOYS/MEN AND GIRLS/WOMEN. Notice that, although an average boy's/man's visuospatial skills are higher than an average girl's/woman's, scores for the two gender groups almost entirely overlap. Not all boys/men have better visuospatial skills than all girls/women—the overlap indicates that, although the average boy's/man's score is higher, many girls/women outperform most boys/men on such tasks.

study of seventh-graders' beliefs about math found that girls' perception that teachers had gendered expectations favoring boys over girls was linked to girls having more negative math beliefs and lower math achievement (McKellar & others, 2019). Also, in this study, when girls perceived that the math curriculum was personally meaningful and relevant for them, they had more positive math beliefs and higher math achievement.

Socioemotional Similarities and Differences Are "men from Mars" and "women from Venus"? Perhaps the gender differences that most fascinate people are those regarding how boys/men and girls/women relate to each other as people. For just about every imaginable socioemotional characteristic, researchers have examined whether there are differences between boys/men and girls/women. Here we examine three that have been closely studied: (1) aggression, (2) emotion and its regulation, and (3) people versus thing orientation.

Aggression One of the most consistent gender differences identified is that boys are more physically aggressive than girls (Hyde, 2017). The difference occurs in all cultures and appears very early in children's development (Dayton & Malone, 2017). The difference in physical aggression is especially pronounced when children are provoked.

Although boys are consistently more physically aggressive than girls, might girls show as much or more verbal aggression, such as yelling, compared with boys? When verbal aggression is examined, gender differences typically disappear or aggression is even more pronounced in girls (Eagly & Steffen, 1986).

Recently, increased interest has been directed toward *relational aggression*, which involves harming someone by manipulating a relationship (Brandes & others, 2021). Relational aggression includes such behaviors as trying to make others dislike a certain individual by spreading malicious rumors about the person (Chen & Cheng, 2020). Relational aggression increases in middle and late childhood (Dishion & Piehler, 2009). Mixed findings have characterized research on whether girls show more relational aggression than boys, but one consistent finding is that relational aggression comprises a greater percentage of overall aggression for girls than for boys (Putallaz & others, 2007). And a research review revealed that girls engage in more relational aggression than boys in adolescence but not in childhood (Smith, Rose, & Schwartz-Mette, 2010).

What gender differences characterize aggression?
Fuse/Corbis RF/Getty Images

Emotion and Emotion Regulation Gender differences occur in some aspects of emotion (Connolly & others, 2019). Girls/women express emotion more openly than boys/men, are better at decoding emotion, smile more, cry more, and are happier (Gross, Frederickson, & Levenson, 1994; LaFrance, Hecht, & Paluck, 2003). Also, boys/men report experiencing and expressing more anger than girls/women do (Kring, 2000). Further, girls/women are better at reading others' emotions and more likely to show empathy than are boys/men (Blakemore, Berenbaum, & Liben, 2009). In addition, a recent study of adolescents found that girls express more emotional concern for others than boys (Trentini & others, 2021) and a meta-analysis found that girls/women are better than boys/men at recognizing nonverbal displays of emotion (Thompson & Voyer, 2014). Also, a recent study revealed that girls/women are better than boys/men at facial emotion perception across the life span (Olderbak & others, 2019).

An important skill is being able to regulate and control one's emotions and behavior (Dollar & Calkins, 2020). Boys/men usually show less self-regulation than girls/women (Blakemore, Berenbaum, & Liben, 2009). For example, a recent study found that girls had much better self-regulation than boys at 13 to 16 years of age (van Tetering & others, 2020). Low self-control can translate into behavior problems (Schunk, 2020).

developmental **connection**
Emotion
Emotion regulation is a key aspect of children's socioemotional competence, and it changes developmentally. Connect with "Emotional Development and Attachment."

People Versus Thing Orientation Researchers also have found that girls are more "people oriented" and boys are more "things oriented" (Galambos, Berenbaum, & McHale, 2009). In a research review, this conclusion was supported by findings that girls spend more time and energy building relationships, while boys spend more time alone, playing video games, and playing sports; that girls work at part-time jobs that are people-oriented such as waitressing and babysitting, while boys are more likely to take part-time jobs that involve manual labor and using tools; and girls are interested in careers that are more people-oriented, such as teaching and social work, while boys are more likely to be interested in object-oriented careers, such as mechanics and engineering (Perry & Pauletti, 2011). Researchers also have found that adolescent girls engage in more self-disclosure (communication of intimate details about

themselves) in close relationships, are better at actively listening in a conversation than are boys, and emphasize affiliation or collaboration (Leaper, 2015). Adolescent girls are especially likely to engage in self-disclosure and emotional support in friendship to a greater extent than are boys (Leaper, 2013). By contrast, boys are more likely to value self-assertion and dominance than are girls in their interactions with friends and peers (Rose & Smith, 2018). It is important to note that all of these findings do not mean that girls and boys are innately different; all of these differences could be due to sociocultural influences.

Gender Controversy Controversy surrounds the extent of gender differences and what might cause them (Gangestad & Chang, 2020). As we saw earlier, evolutionary psychologists such as David Buss (2019) argue that gender differences are extensive and caused by the adaptive problems people have faced across their evolutionary history. Alice Eagly (2018) also concludes that gender differences are substantial, but she reaches a very different conclusion about their cause. She traces gender differences to social conditions that have resulted in women having less power and controlling fewer resources than men do.

By contrast, Janet Shibley Hyde (Hyde & others, 2019) concludes that gender differences have been greatly exaggerated, with these comparisons being especially fueled by popular books such as John Gray's (1992) *Men Are from Mars, Women Are from Venus* and Deborah Tannen's (1990) *You Just Don't Understand*. She argues that the research indicates girls/women and boys/men are similar on most psychological factors. In a research review, Hyde (2005) summarized the results of 44 meta-analyses of gender differences and similarities. A *meta-analysis* is a statistical analysis that combines the results of many different studies. Gender differences in most areas—including math ability and communication—were either nonexistent or small. Gender differences in physical aggression were moderate. The largest difference occurred on motor skills (favoring boys/men), followed by sexuality (boys/men masturbate more often and are more likely to endorse sex in a casual, uncommitted relationship) and physical aggression (boys/men are more physically aggressive than girls/women are).

Hyde's summary of meta-analyses is unlikely to quiet the controversy about gender differences and similarities, but further research should be conducted to provide a basis for more accurate judgments on this topic. Indeed, later in the chapter, after we discuss "Gender Role Classification," we will explore Hyde and her colleagues' (2019) expanded analysis of the breadth of gender similarities.

developmental **connection**

Nature and Nurture

Bronfenbrenner's ecological theory emphasizes the importance of contexts; in his theory, the macrosystem includes cross-cultural comparisons. Connect to "Introduction."

Gender in Context In thinking about gender, it is important to consider the context of behavior (Erickson-Schroth & Davis, 2021). Gender behavior often varies across contexts. Consider helping behavior. Men are more likely to help in contexts in which a perceived danger is present and they feel competent to help (Eagly & Crowley, 1986). For example, men are more likely than women to help a person who is stranded by the roadside with a flat tire; automobile problems are an area in which many men feel competent. In contrast, when the context involves volunteering time to help a child with a personal problem, women are more likely to help than men are, because there is little danger present and women feel more competent at nurturing. In many cultures, women show more caregiving behavior than men do.

In China, females and males are usually socialized to behave, feel, and think differently. The old patriarchal traditions of male supremacy have not been completely uprooted. Chinese women still make considerably less money than Chinese men do, and, in rural China (such as here in the Lixian Village of Sichuan), male supremacy still governs many women's lives.
CharlineX China Collection/Alamy Stock Photo

Context is also relevant to gender differences in the display of emotions (Pang & Baumann, 2020). Consider anger. Men are more likely to show anger toward strangers, especially other men, when they think they have been challenged. Men also are more likely than women to turn their anger into aggressive action, especially when their culture endorses such action (Tavris & Wade, 1984).

In many cultures around the world, traditional gender roles continue to guide the behavior of boys/men and girls/women (Qu & others, 2020; Reichard & others, 2020). In China and Iran, for instance, it is still widely accepted for boys/men to engage in dominant behavior and girls/women to behave in subordinate ways. In a recent study of eighth-grade students in 36 countries, in every country girls had more egalitarian attitudes about gender roles than did boys (Dotti Sani & Quaranta, 2017). In this study, girls had more egalitarian gender attitudes in countries with higher levels of societal gender equality. Many Western cultures, such as the United States, have become more flexible about gender behavior and allow for more diversity. For example, although a

girl's father might promote traditional femininity, her friends might engage in many traditionally masculine activities and her teachers might encourage her to be assertive.

In the United States, the cultural backgrounds of children and adolescents influence how boys and girls will be socialized. In one study, Latinx adolescents were socialized differently as they were growing up (Raffaelli & Ontai, 2004). Latinx girls experienced far greater restrictions than Latinx boys in having curfews, interacting with people of a different gender, getting a driver's license, getting a job, and being involved in after-school activities.

androgyny The presence of positive masculine and feminine characteristics in the same individual.

transgender A broad term that refers to individuals who have a gender identity that differs from the gender associated with the sex assigned to them at birth.

GENDER-ROLE CLASSIFICATION

Not long ago, it was accepted that boys should grow up to be masculine (powerful, assertive, for example) and girls to be feminine (sensitive to others, caring, for example). In the 1970s, however, as both women and men became dissatisfied with the burdens imposed by their stereotypic roles, alternatives to femininity and masculinity were proposed. Instead of describing masculinity and femininity as a continuum in which more of one means less of the other, it was proposed that individuals could have both masculine and feminine traits.

Androgyny

The trend toward non-binary thinking about personality traits led to the development of the concept of **androgyny,** the presence of positive masculine and feminine characteristics in the same person (Bem, 1977; Spence & Helmreich, 1978). An androgynous boy might be assertive (masculine) and nurturing (feminine). An androgynous girl might be powerful (masculine) and sensitive to others' feelings (feminine). Measures have been developed to assess androgyny, such as the Bem Sex Role Inventory (Bem, 1977).

Gender experts such as Sandra Bem (1977) argue that androgynous individuals are more flexible, competent, and mentally healthy than their masculine or feminine counterparts. To some degree, though, which gender-role classification is best depends on the context involved. For example, in close relationships, feminine and androgynous orientations might be more desirable. One study found that girls and individuals high in femininity showed a stronger interest in caring than did boys and individuals high in masculinity (Karniol, Grosz, & Schorr, 2003). And a recent study found that androgynous boys and girls had higher self-esteem and fewer internalizing problems than masculine or feminine individuals (Pauletti & others, 2017).

However, masculine and androgynous orientations might be more desirable in traditional academic and work settings because of the achievement demands in these contexts. In a recent analysis, this emphasis on considering contexts in understanding gender identity was described in terms of *functional flexibility*. In this view, gender identity is positively linked to adjustment, and competence involves flexibility in adapting to specific situations (Martin & others, 2017).

Transgender

Transgender is a broad term that refers to individuals who have a gender identity that differs from the gender typically associated with their sex assigned at birth (Lelutiu-Weinberger, English & Sandanapitchai, 2020). For example, an individual may be assigned female at birth and identify as a boy or man, or be assigned male at birth and identify as a girl or woman. An individual may also be assigned female or male and identify as another gender outside of the girl/woman versus boy/man gender binary. A transgender identity of being assigned male but identifying as a girl or woman is much more common than the reverse (Zucker, Lawrence, & Kreukels, 2016). Transgender persons with a nonbinary identity (see below) also may not want to be called "he" or "she" but prefer a gender-neutral pronoun such as "they" or "ze."

Because of the nuances and complexities involved in such gender categorizations, some experts have recently argued that a better overarching umbrella term might be *trans* or *gender diverse* to identify a variety of gender identities and expressions different from the gender typically associated with the sex that was assigned at birth (Galupo & others, 2019; Sinclair-Palm, 2019). The variety of gender identities include binary transgender identities (for example, transgender girl/woman, transgender boy/man) and nonbinary gender identities (individuals who have a gender identity that is outside the girl/woman and boy/man binary, such as gender queer individuals who are not exclusively masculine or exclusively feminine and gender-nonconforming individuals whose behavior/appearance does not conform to social expectations for what is appropriate for their gender).

Mack Beggs, a 17-year-old high school student who is transitioning from female to male, won the Texas state wrestling championship for girls in the 110-pound weight class in 2017. The transgender wrestler is taking testosterone treatments as part of the gender transition to enhance male characteristics. Some of the wrestler's opponents have said that Mack has an unfair advantage among girls because of the testosterone treatments. Mack never lost a wrestling match during the 2016–2017 school year, going 52-0 in matches, all in the female division. *What do you think? Should Mack have been allowed to wrestle in the girls' division?*
Leslie Plaza Johnson/Icon Sportswire/Getty Images

What characterizes transgender individuals?
Johnny Greig/E+/Getty Images

In addition, the term *two-spirit* is used by some indigenous North Americans to describe gender-diverse individuals who are perceived to have spirits from both women and men. *Cisgender* can be used to describe individuals whose gender identity and expression conform to their sex assigned at birth (Hyde & others, 2019). Although the term "transsexual" has been used historically to refer to transgender people, it is now regarded as outdated and may be perceived as offensive by some transgender individuals.

As with cisgender individuals, transgender individuals can have any sexual orientation. A research review concluded that transgender youth have higher rates of depression, suicide attempts, and eating disorders than their cisgender peers (Connolly & others, 2016). Among the explanations for higher rates of mental health concerns are the distress of living in the wrong body and the discrimination and misunderstanding encountered by gender-minority individuals (Bretherton & others, 2021; Yockey, King, & Vidourek, 2021). In a recent study of transgender individuals, gender affirmation—being recognized as one's gender identity, gender expression, or gender role—was associated with a lower probability of suicidal ideation and psychological distress, while discrimination was linked to a higher probability of suicidal ideation and psychological distress (Lelutiu-Weinberger, English, & Sandanapitchai, 2020). And another recent study confirmed that victimization and discrimination predicted increased suicidal ideation, while community connectedness reduced suicidal ideation (Rabasco & Andover, 2021).

Among youth who identify themselves as transgender persons, the majority eventually adopt a gender identity in line with the body into which they were born (Byne & others, 2012; King, 2020, 2022). Some transgender individuals seek gender-affirming surgery to change their physical body to more closely match their gender identity, but many do not. Some choose to receive hormonal treatments, such as assigned females who use testosterone to enhance their masculine physical characteristics or assigned males who use estrogen to increase their feminine physical characteristics. Yet other transgender individuals opt for another, broader strategy that involves choosing a lifestyle that challenges the traditional view of having a gender identity that fits within one of two opposing categories (Waryold & Kornahrens, 2020).

A special concern is the discrimination directed at trans individuals (Sherman & others, 2020). A recent study found that a majority of transgender individuals had experienced discrimination in the last year and those with greater exposure to discrimination were more likely to develop depression and anxiety symptoms (Puckett & others, 2020). Estimates indicate that 40 percent or more of transgender individuals have attempted suicide at least once in their lives (Dickey & Budge, 2020). Because transgender individuals experience considerable discrimination, it is important that society provide a more welcoming and accepting attitude toward them (Vargas, Huey, & Miranda, 2020). Also, recent research indicates that psychotherapy targeting internalized stigma and non-affirmation experiences can be effective in reducing gender-related stress and improving resilience (Budge, Sinnard, & Hoyt, 2020). To read about one individual who conducts research and psychotherapy with transgender individuals, see the *Connecting with Careers* interlude.

GOING BEYOND GENDER AS BINARY

In a number of places in our coverage of gender, we have indicated that the long-existing (for more than a century) concept of gender as having just two categories—boys/men and girls/women—is being challenged. In a recent analysis, leading expert Janet Shibley Hyde and her colleagues (2019) described a number of aspects of gender where this challenge is occurring. These include the following developments: (1) neuroscience research indicates the presence of a gender mosaic rather than "his or her" brains that are highly different; (2) endocrinology research reveals more hormonal similarities in males and females than had been previously envisioned; (3) recent conceptual changes in gender role classification go far beyond characterizing individuals as masculine or feminine and add a number of new gender identity categories such as transgender and nonbinary; (4) developmental research indicates that the tendency to view gender as a binary category is not due only to biological factors but also culturally determined and malleable. Further, gender categories are not mutually exclusive—an individual can identify with more than one category. Also, gender categories are fluid because an individual's gender identity can change over time. Each of the ideas described here reflects a substantial change in how gender is conceptualized and reflected in individuals' daily lives, but as we indicated earlier in the chapter there is still controversy about the extent of gender similarities and differences.

connecting with careers

Stephanie Budge, Transgender Researcher and Psychotherapist

Dr. Stephanie Budge is a leading expert on transgender research, issues, and psychotherapy. She is a professor in the Department of Counseling at the University of Wisconsin–Madison, where she obtained her Ph.D in counseling psychology. Her research examines emotional development and coping in transgender youth and adults, as well as psychotherapy with transgender clients. Dr. Budge also works nationally and internationally in training individuals to provide help related to LBGTQ issues, with a focus on increasing practitioners' self-efficacy, knowledge, and skills.

Courtesy Dr. Stephanie Budge

At the University of Wisconsin–Madison, Dr. Budge has given pro-bono therapy to transgender youth and adults. Dr. Budge has received the LGBTQ Outstanding Community Contributions award from the American Psychological Association and the LGBT Early Career Award from the Society for Counseling Psychology. She is currently associate editor of two journals: *Psychotherapy* and *Psychology of Sexual Orientation and Gender Diversity*. Dr. Budge also serves on the editorial board of the *International Journal of Transgender Health*.

3 Gender Development Through the Life Span

LG3 Describe the development of gender through the life span.

Childhood | Adolescence | Adulthood and Aging

In this section we will focus further on gender-related developmental changes in the childhood years. In addition, we will look at changes that take place in adolescence and adulthood, including the influence of gender roles in adolescence and some of the ways that gender roles might shift as people age.

CHILDHOOD

The amount, timing, and intensity of gender socialization differs for girls and boys (Beal, 1994). Boys receive earlier and more intense gender socialization than girls do. The social cost of

Are gender roles more flexible for boys or for girls?
(*Top*): Andrey Bandurenko/Alamy Stock Photo; (*bottom*): Design Pics/SuperStock

deviating from expected gender roles is higher for boys than for girls, in terms of peer rejection and parental disapproval. Imagine a girl who is wearing a toy holster, bandanna, and cowboy hat, running around in the backyard pretending to herd cattle. Now imagine a boy who is wearing a flowered hat, ropes of pearls, and lipstick, pretending to cook dinner on a toy stove. Which of these do you have a stronger reaction to—the girl's behavior or the boy's? Probably the boy's. Researchers have found that "effeminate" behavior in boys elicits more negative reactions than does "masculine" behavior in girls (Martin, 1990).

Boys might have a more difficult time learning the masculine gender role because models for men are less accessible to young children and messages from adults about gender roles are not always consistent. For example, most mothers and teachers would like boys to behave in masculine ways, but also to be neat, well mannered, and considerate. However, fathers and peers usually want boys to be independent and to engage in rough-and-tumble play. These mixed messages make it difficult for boys to figure out how to act.

Although gender roles have become more flexible in recent years, the flexibility applies more for girls than for boys (Beal, 1994). Girls can count on receiving approval if they are ambitious, competitive, and interested in sports, but relatively few adults are equally supportive of boys' being gentle, interested in fashion, and motivated to sign up for ballet classes. Instrumental traits and masculine gender roles may be evolving into a new norm for everyone.

Concern about the ways in which boys are being brought up has been called a "national crisis of boyhood" by William Pollack (1999) in his book *Real Boys*. Pollack says that little has been done to change what he calls the "boy code." The boy code tells boys they should not show their feelings and should act tough, says Pollack. Boys learn the boy code in many contexts—sandboxes, playgrounds, schoolrooms, camps, hangouts—and are taught the code by parents, peers, coaches, teachers, and other adults. Pollack, as well as many others, argues that boys would benefit from being socialized to express their anxieties and concerns and to better regulate their aggression.

ADOLESCENCE

Early adolescence is another transitional point that seems to be especially important in gender development (Yang & others, 2020). Young adolescents have to cope with the enormous changes of puberty. These changes are intensified by their expanding cognitive abilities, which make them acutely aware of how they appear to others. Relations with others change extensively as dating begins and sexuality is experienced.

As girls and boys undergo the physical and social changes of early adolescence, they must come to terms with new definitions of their gender roles (Pascoe, 2017). During early adolescence, individuals develop the adult, physical aspects of their assigned sex. Some theorists and researchers have proposed that, with the onset of puberty, girls and boys experience an intensification of gender-related expectations. Puberty might signal to socializing others—parents, peers, and teachers, for example—that the adolescent is beginning to approach adulthood and therefore should begin to behave in ways that more closely resemble the stereotypical adult woman or man. The **gender-intensification hypothesis** states that psychological and behavioral differences between boys and girls become greater during early adolescence because of increased pressure to conform to traditional masculine and feminine gender roles (Galambos, 2004; Hill & Lynch, 1983).

Some researchers have reported evidence of gender intensification in early adolescence (Hill & Lynch, 1983; Yang & others, 2020), but others have found no evidence for intensification in masculinity or femininity in young adolescents (Priess, Lindberg, & Hyde, 2009). The jury is still out on the validity of the gender-intensification hypothesis, but research has raised questions about its accuracy (Galambos, Berenbaum, & McHale, 2009).

Gender intensification may create special problems for boys. Adopting a strong masculine role in adolescence is increasingly being found to be associated with problem behaviors. Joseph Pleck (1995) argues that definitions of traditional masculinity include behaviors that do not have social approval but nonetheless validate the adolescent boy's masculinity. That is, in the adolescent boy culture, adolescent boys perceive that they will be thought of as more masculine if they engage in premarital sex, drink alcohol, take drugs, and participate in delinquent activities. One study revealed that both boys and girls who engaged in extreme gender-typed (hypergender) behaviors had lower levels of school engagement and school attachment (Ueno & McWilliams, 2010).

gender-intensification hypothesis The view that psychological and behavioral differences between boys and girls become greater during early adolescence because of increased socialization pressures to conform to traditional gender roles.
